PREFACE

A Word from the Editor-in-Chief

Dear colleagues,

In your hands are the Proceedings of the 9th International Scientific Agricultural Symposium "AGROSYM 2018" held on 4-7 October 2018 in Jahorina, Bosnia and Herzegovina. The Symposium gathers about 1200 participants from 85 different countries and organizers received over 1200 abstracts/full papers. Symposium themes covered all branches of agriculture and were divided into seven sessions: 1) Plant production, 2) Plant protection and food safety, 3) Organic agriculture, 4) Environmental protection and natural resources management, 5) Animal husbandry 6) Forestry and Agro-forestry, and 7) Rural Development and Agro-economy.

In the plenary lectures was presented the importance of new information and communication technologies for agriculture in the 21st century and biological protection in plant production. Furthermore, a particular attention was devoted to avoiding knowledge waste through networking and partnership.

Agriculture has a complex relationship with natural resources and the environment, thus attributing specific environmental effects to agriculture is difficult and not fully understood. Today, it is obvious that conventional methods of agricultural production, in addition to providing sufficient food and other products, have led to a number of negative impacts, including direct or indirect effects on human health. Excessive use of agrochemicals can cause various disorders in the biological equilibrium of agroecosystems and beyond. These negative impacts raise serious questions about long-term sustainability of high-input agriculture. Measures to protect soil and water in agriculture include comprehensive and complex undertakings and pre-planned measures. These problems are a constant reason for 'popularisation' of all ecological trends in agriculture (e.g. organic agriculture, permaculture, biodynamic agriculture, conservation agriculture, regenerative agriculture, integrated farming, agroecology, etc.). Meanwhile, there are also calls for a genuine, deep transformation of agro-food systems that goes beyond 'ecologisation' of agricultural production. All these developments in agricultural research field, as well their implications on farmers' fields, were discussed during the 4 days of AGROSYM 2018.

All papers included in the Proceedings were peer-reviewed. Full texts of the accepted contributions are available in electronic form on AGROSYM website (http://agrosym.unssa.rs.ba).

I hope that the Proceedings will be useful to many agriculturalists and to those engaged in related fields and enable better collaboration of scientists, researchers and producers.

Many thanks to all the authors, reviewers, session moderators and colleagues for their help in editing the Proceedings "AGROSYM 2018". Special thanks go to all co-organizers for their unselfish collaboration and comprehensive support.

East Sarajevo, 07th October 2018

Prof. Dušan Kovačević, Editor-in-Chief

PLANT PRODUCTION

STUDY ABOUT SOME ECOLOGICAL ASPECTS OF GRAIN OAT CULTIVARS (Avena sativa L.) IN ALBANIAN CONDITIONS

Abstract

Concentrate oat is a very important such as forage crop for animals and food for people. It is a plant with a very wide spreading range and with a high degree of eligibility to ecological conditions. Oat is a crop with high protein content, carbohydrates, fats, vitamins and other mineral elements, which make it a high-value biological food especially for animals but also for humans. It compose the food base for many ruminant animals as there is a balanced content of the main nurient elements. But recently it is being successfully used as human food by replacing other cereals and this has actually become a tradition as it is a healthy, balanced, and high-value biological food. The oat represent a high agronomic performance compare to many other cereals till it is a plant that plays an important role in cereals cultivation technology, such as plant rotation, plant mixtures and as the main single crop cultivation. It is a resistant plant to biotic and abiotic stresses and as such exhibits good adaptability to climate and soil conditions and to climate change. Today when society has become more vulnerable to environmental problems, a change in the situation of the agriculture sector and sustainability is more than required. An important factor in actual situation is the change in the structure of cultivars. But despite the importance of this crop, the collection of cultivars in production in Albania is relatively poor, although a large number of hybrids with high production potential have entered from other countries. The objective of this study was to compare differnet oats cultivars as "Këmishtaj" and "Lushnja x Kamza", native cultivars and some other cultivars coming from some Western countries as "Mansholt I", "Makte Haver Oversalt", "Torpan" and "Bendo" (Holland); "Abed Minor" (Denmark) and "Argus" (Sweden), which are widespread in production in these countries and have been successful in various environmental conditions for their biomorphological aspects, food quality, production levels, adaptation abillity, resistance and resilience. This study evidence that the "Këmishtaj" cultivar has yielded an average of 2,55 t/ha^{-1}, the "Torpan" cultivar 2,5 t/ha^{-1} and "Argus" and "Abed Minor" yielded respectively 2,3 t/ha^{-1} and 2,1 t/ha^{-1}, which shows that they are well adapted to the conditions of Albania and can be successfully used in the production.

Keywords: *oat (Avena Sativa L.), cultivars, productivity, hybride, adaptation*

Introduction

Oat *(Avena Sativa L.)* is a crop that is part of cereals group even it is cultivated cultivated less than the others. It is a herbaceous plant belonging to the graminaceae family. From the large number of its species in cultivation there are found only two species *Avena Sativa L.* and *Avena Byzantina L*. (Suttie et al., 2004). Te oat is cultivated at ancious time. It is cultivated in Egypt and in Europe. According to De Candolle (1883) the cultivated cultivated originated from Europe. Vavilov had found many varieties of *A. Sativa* in Mongolia and in China (Vavilov 1920-1940).

Oat is widely cultivated all over the world, even though there has been a decrease in the cultivated area and its production over the years. The main production country's is the EU with 7,999 thousand tons followed by Russia with 4,027 tons and then Canada 2,812 tons

compare to 21,391 thousand tons of total worlds production (USDA, United States Department of Agriculture, 2013). Researchers have identified the oat as a healthy diet crop for humans and animals (McDonald et al., 1992). It is cultivated mainly as forage crop for cattle nutrition which is used as concentrated food for animals or as a biomass for direct grazing (Suttie et al., 2004) since it is considered as high-quality food for livestock animals (Givens and Brunnen, 1987).

During recently years are the society is changed nutritional behaviors and the oat has tremendously increased for widely used as a dietary diet for human, thanks to the balanced content of its elements. It is highly valued for its nutritional values in human nutrition (Redaelli et al., 2005).

Oat is rich in protein (15-24%), fats (9%), fibber (12%) and carbohydrates. It contains many mineral salts such as calcium, potassium, magnesium and iron. This makes it successfully used as food for people in order to regulate their metabolic processes. (Bellato, 2013). It is considered as a food with potential free gluten content and is used in the diet of some people (Sadiq Butt et al, 2008; Koskinen et al., 2009). It is used in food processing products such as flakes, biscuits, breads and extracts of oils used in the pharmaceutical and cosmetic industries (Valentine, 1990, 1995). Oat it is used also in distillation of whiskey (Viggiani & Pezzi, 2002).

In cultivation technologies, it can be cultivated as a simple culture or in combination with other crops. For this reason in the structure of forage crops for fodder or green mass production it occupies an important place especially in the agricultural crop circulation. This is due to the fact that in comparison with other cereals it has a great mass increase in its abilities (Baldoni et al., 2000).

In recent years it is ncreased the demand for the qualitative oat seeds production based on the increase of oat cultivation surfaces. Also the demand from farmers for new cultivars with high grain quality and biomass production has increased extremly. This demand can be achieved through genetic improvement or selection, although recently on genetic improvement programs it is working more to get higher amounts of protein (Peltonen et al., 2004).

In account to the large number of cultivars used today in the world, such as *"Mansholt I", "Nakte Haver", "Overasalt", "Torpan", "Bendo", "Abed Minor"* and *"Argus"* etc. in Italy, *"Argentina", "Alcudia", "Genziana", "Primula Bioda", "Corneil", "Donata", "Fulvia", "Hamel", "Tenebra", "Teo DB40"* (Redaelli et al., 1999; 2013). The oat varietal structure in Albania is poor, since its cultivation are is not large and the *"Këmishtaj"* and *"LxK"* cultivars are the main ones.

In recent years have been introduced hybrid cultivars from overseas which have been studied in advance in the collection trails for different indicators and in particular those of production. Hybrid cultivators produce more, but they do not have the characteristics of traditional cultivars such as nutrient content, resistance to pests and diseases, especially for climatic fluctuations.

Based on some features and indicators, some cultivars have been distinguished from their testing in collection trails because they have interesting indicators for production as well as they are high productive and are resistant to crashes.

These new cultivars for our country, before being recommended for spreading in production, must be subjected to competitive trails (putting them into evidence of zoning comparison). From the preliminary work in the collection trails, the following cultivars have been distinguished: "*Mansholt I"*, "*Nakte Haver",* "*Overasalt"*, "*Torpan"* and *"Bendo"* (Netherlands), "*Abed Minor"* (Denmark) and "*Argus"* (Sweden) which have been put together in comparative trail together with two cultivars made in Albania, "*Kemishtaj"* and "*LxK"*. In the comparative trail, two other cultivars have been added, one produced in the country ("*MVS"* 2008), which is spreaded and is cultivated in the southern area of Albania

and the other from Macedonia ("*MMS"*, 2008). These two cultivars are not studied before for the conditions of the Albanian coastal area.
The main purpose of this research has been the testing of cultivars genetically differencies to look also at the genotype response and on the evaluation of the best cultivars for the production and sustainability indicators to be recommended for the improvement of the varietal structure that is actualy in cultivation in Albania acording to different pedoclimatic zones.

Material and Methods

The experiment was set up in the Experimental Base of Center for Agriculture Technology Transfer of Fushe Kruje. The soil type is aluvional light ash brown. The experiment was set up in 8 variants and 4 replicas, according to the randomized block scheme. Each variant represents a cultivar and the size of each variant was 10 m^2 as follows:

V1 – "Këmishtaj" Cultivar (Local)
V2 – "Lushnja x Kamza" Cultivar (Local)
V3 – "Mansholt I" Cultivar (Holland)
V4 – "Makte Haver Oversalt" Cultivar (Holland)
V5 – "Torpan" Cultivar (Holland)
V6 – "Bendo" Cultivar (Holland)
V7 – "Abed Minor" Cultivar (Denmark)
V8 – "Argus" Cultivar (Sweden)
V9 – "MVS – 2008" Local cultivar
V10 – "MMS – 2008" Foreing cultivar

The applied technology is roughly the same as that is used in the common production. The previous crop has been alfalfa. Land plowing was carried out in October at a depth of 21 - 35 cm. For the preparation of the planting bed were passed twice with discs. In the base fertilizer is used 400 kg/ha^{-1} granulated superphosphate which is distributed in two layers. About one-third of the amount is thrown before the plowing and 2/3 before the discs. Planting was done at the beginning of November, on 05/11/2008 with seed rate of 160 - 180 kg/ha^{-1}. Planting is done by hand, with lines at a distance of 30 cm between rows and the seed was dispersed in chains way in the row. Drainage: Immediately after oat planting was carried out the drainage proceedings of the experimental field and the drainage system has been kept functional during all the oat vegetation period. Additional fertilization: 300 kg/ha^{-1} nitrogen fertilizer (ammonium nitrate with 32% a.m.) was used three times. The first time was thrown into the phase of two - three leaves of the fraternal start with the dose of 80 kg/ha^{-1}, the second time at the fraternal full - fledged start phase with 100 kg/ha^{-1} and the third time at the intensive lifting stage with the dose of 120 kg/ha^{-1}. Attention is also paid to fighting weeds. Combating bad weeds is done through mechanical methods. The harvest is carried out in the full baking phase and with each variant is performed separately. After tiring and cleaning is done the weighing individually of each variant of the experiment.

Results and discussion

During the vegetative period, based on the methodology approach the datas were recorded for the passage of phenological phases (germination, fraternallity, raising, earing, flowering and maturity). From recording of these data it represent that all cultivars compared do not present significant changes in the transition of these phases, so all cultivars have the same vegetative cycle ranging from 196 to 200 days, with small differences of 3 - 4 days.

Observations and notess have also kept for the sustainability of low temperatures, falling and resistence from diseases and pests.
For low temperature stability is done the counting of plants on the trai area before and after wintering. For the year under study no crops are distinguished for this indicator, as the minimum temperatures of the year were not in those limits causing damages during their vegetation.
As for their resistance to plant falling, which is one of the most important indicators in this trend, (assessment is done from 1st up to 5th classes) there are evidenced differences between the cultivars. Thus, the "*Këmishtaj*" cultivar is the most sustainable one against this phenomenon. The cultivars sustainability representes also the *"Torpan"* (Netherlands), *"Argues"* (Denmark) and *"Abed Minor"* (Sweden) cultivars, while the *"LxK"* cultivar is the least-resistent from this phenomenon, where the signs of falling were evidenced from the beginning of the rise and falling arrives till at 4th class.

Figure no. 1. "*Këmishtaj"Cultuvar (fall "0" class)*

Figure no. 2. "*LxK" Cultivar (fall "3" Class)*

In comparative trail are evaluated and other phenotypic indicators such as plant color, presence of anthocyanin, presence of thistles, panicula and grain color as well as biometric indicators.

Table no. 1 Biometric Plant Indicators

No. Variants	Cultivars	Plant length in cm (average)	Length of the main spike in cm	Seed no. in main spike	Weight of main spike (g)	Weight of 1000 seeds (g)
1	*Këmishtaj*	155	27	210	4.4	22
2	*Lushnja x Kamza*	170	35	120	2.4	20
3	*Mansholt I*	165	27	160	3.2	20
4	*Nakte Haver Oversalt*	180	38	180	3.5	19.5
5	*Torpan*	155	30	180	3.9	22
6	*Bendo*	160	30	140	2.8	20
7	*Abed Minor*	170	32	180	4.1	23
8	*Argus*	165	32	170	3.9	23
	Average	**165**	**31.37**	**167.5**	**3.52**	**21.18**

Referring to the data we conclude that all the tested cultivars, based on the absolute weight, are part of the oats group with small seeds and that compared with cultivation oat cultivars studies conducted in other nearby countries (Italy) where the absolute weight is 33.0 g (Redaelli et al., dal 2002 al 2013). Among the tested cultivars there are differences in their absolute weight. Referring to the data of the table above, we conclude that all the tested cultivars, starting from their absolute weight are part of the oats group with small seeds. However, among the tested cultivars there are differences in their absolute weight. In general, there is a correlation linkage in terms of the number grains in the paniculas, the weight of the main spike and their absolute weight, with the yield for each cultivar. Thus, cultivars with a greater number of grains in the main spike and the greater absolute weight result with higher yield per surface unit.

The length of the main plant it is an important indicator for the oat crop, which also affects into its fall resistance. Thus generally short-to-moderate legth cultivars are more resistant to fall than the tall cultivars. Thus the cultivars of the "*Këmishtaj*", *"Torpan"* and *"Argues"*, which are shorter than the other tested cultivars are more resistant to the falling phenomenon. However, they are longer compared to some cultivars in nearby countries as Italy where the average length goes to 107 cm (Redaelli et al., dal 2002 al 2013), in Slovenia 147.8 cm and Morocco 144.1 cm (Toshinobu Morikawa, et al. 2016), from 165 cm that are the tested cultivars. Regarding qualitative indicators such as plant color at different stages of vegetation, the presence of anthocyanin, the presence of flips, the paniculate shape and the grain color, the cultivars tested are peresented with significant variation. Thus, for cultivars, "*Këmishtaj*", *"Torpan"*, *"Bendo"* and *"Mineral Abt"* the color of the plant is dark green, for *"LxK"*, *"Nakte Haver"* cultivars the plant color is common green into light one, while for the cultivars *"Mansholt I"* and *"Argus"* it is common green. The presence of flips is found in *"LxK"* and *"Nakte Haver"* cultivars. In terms of grain color it is evidenced the yellowish-white such as *"Mansholt I"* and *"Bendo"* cultivars, yellow as "*Këmishtaj*", *"Torpan"* and *"Argus"*, yellow in brown into *"Abed Minor"* and *"LxK"* cultivars.

The variation is also visible in the form of panculas. The *"LxK"* cultivar (photo no.3) has an open panicula with almost straight edges. The "*Këmishtaj*" cultivar (photo no. 4) has flagged panicula, *"Argus"* and *"Abed Minor"* cultivars (photo no. 5) have right panicula with a bushy twist.

Figure no. 3. Type of panicula on "*Kemishtaj", "LxK"* and "*Argus"* Cultivars

The most important test indicator that is evaluated during the zonal test is the realized production per surface unit (yield).

Table no 2. Realizyed yield for each cultivar (t/ha).

Cultivars/Variants	Repetitions				Variants amount	Average Yield (q/ha)
	I	II	III	IV		
Këmishtaj (V_1)	2.45	2.6	2.5	2.65	10.2	***2.55***
Lushnja x Kamza (V_2)	1.3	1.1	1.15	1.25	4.8	*1.2*
Mansholt I (V_3)	1.75	1.8	1.6	1.65	6.8	*1.7*
Nakte Haver Oversalt (V_4)	1.9	1.85	1.95	1.9	7.6	*1.9*

From statistical data processing, the factual F value for repetitions is smaller than the theoretical F values, for both levels of propiability. This shows that soil fertility has not affected the variability of the experiment. The factual F value for variants is greater than the theoretical F values for both propiability levels. This indicates that the changes in the experiment is the effect of the variants, ie the test cultivars or the factor being put into study. Comparison of the data in Table no. 2 shows that the highest production indicators have the cultivars of "*Këmishtaj"* with 2,55 t/ha^{-1}, *"Torpani"* with 2,5 t/ha^{-1} and *"Argus"* and *"Abed Minor"*, which have respectively 2,3 t/ha^{-1} and 2,2 t/ha^{-1}; even though with lower production than the data coming from studies conducted in other countries (3,97 t/ha^{-1}) from the conventional systems in Latvia (Ingver A. et al.,2008); or (4,50 t/ha^{-1}) in close countries as Italy (Redaelli et al., dal 2002 al 2013), but with significative different ecological conditions. We point out that the climate conditions of the test year were not adequate according to the oat biological requirements. The period of panicula until full ripening is accompanied by numerous rainfall and strong winds. These factors have negatively affected for the achieved yields by the cultivars and their falling rate. This is also argumented by comparing with of the oat biological production capacity.

Conclusions

Testing of new cultivars to spread them in the production under the conditions of poor oat strucure cultivars in Albania is a question of imediate necessity.

From cultivar testing it result that the "*Këmishtaj" cultivar* represents higher productivity indicators with average yield of 2,55 t/ha^{-1}, followed by *"Torpan"* cultivar with a yield of 2,5 t/ha^{-1} and then followed by *"Argus"* and *"Abed Minor"* cultivars with yields of 2,3 t/ha^{-1} and 2,1 t/ha^{-1}.

The production levels of these cultivars are good for the conditions of Albania but are below the average of other countries.

In cultivation testing, the pedoclimatic conditions should be carefully evaluated as they affect production indicators, sustainability and other quality indicators of cultivars.

The above-mentioned cultivars with good quantitative and qualitative indicators should be recomended for the Mediterranean field area of Albania, since they enrich the varietal structure of oat cultivars.

The introduction into cultivation practice of these cultivars will enable the expansion of the cultivated area and will increase its production potential as one of the most important cereals for human and animal feed.

Abstract

The aim of our work was to research the influence of agro-ecological factors on quality of nectarine during 2015 and 2016. We conducted research on three different locations in Herzegovinian area. On the locations Stolac, Mostar and Čapljina, we researched plantations of two nectarine cultivars *Big Top* and *Caldesi 2000.* The content of ash, dry matter, total acidity and the content of total sugar in nectarine fruit showed statistically important differences compared with years and locations of studied cultivars. The cultivar *Big Top* had the highest value of dry matter and total acidity on the location of Stolac (15,14 and 0,72%, respectively) The highest content of ash was on the location of Mostar (1,61%), and the highest value of total sugar was registered on the location of Čapljina (11,99%). The values of all the tested parameters were higher in 2015 compared to 2016. The sort *Caldesi 2000* had the highest value of dry matter on the location of Stolac (12,92%). The highest value of ash and the total sugars were registered on the location of Mostar (0,66 and 10,6%, respectively). The highest value of total acidity was registered on the location of Čapljina (1,2%) and the highest value of the total sugar was registered on the location of Mostar (10,6%). As far as the location is concerned, the Caldesi 2000 cultivar is more suitable for the Mostar area. At locations of Stolac and Čapljina both cultivars are suitable for breeding.

Key words: *nectarine, fruit quality, Big Top, Caldesi 2000.*

Introduction

Nectarine is subsort of peach, it has got smooth skin and that is actually difference between peach and nectarine. By crossing and mixing different sorts, we can get nectarines that have the same size as usual peaches, they are also red and they are very sweet as well. Their taste is stronger than the taste of usual peaches. They are important part of daily diet, they have low energy values, a variety of natural sugars, as the source of antioxidant. The Herzegovinian area is very good for growing nectarines, and they are often consumed during summer time. We chose two sorts *Big Top* and *Caldesi 2000*, in order to define quality based on chemical parameters of their fruit. We can evaluate the nectarine fruit using different methods. The methods used in the research are the following: chemical analysis (chromatography values of nectarines fruit), taste or sensory attributes, including fruit analysis (color, texture, juiciness) and organoleptic values of nectarines fruit, and physical values as well (Robertson and coworkers, 1989).

Material and Methods

The field experiment was carried out in the plantation of nectarines in the area of Čapljina, Stolac and Mostar. All experimental researches related to physical and chemical content of nectarines fruit have been done on the sort *Caldesi 2000* and *Big Top.* We did this research during two vegetations: in 2015 and in 2016. Chemical analysis of nectarines fruit were done in Federal Institute for Agriculture Sarajevo. Following chemical parameters were researched: ash content, dry matter, content of total acid, and content of total sugar. Total sugar content was determined by volumetric method by "Luff - Schrool".
Total acidity was determined by potentiometric titration with sodium hydroxide solution

In this paper, the drying method was used at the temperature of 105 ° C. This procedure determines the remainder of the sample after drying at 105 ° C to constant mass. The statistical significance of the quantitative values is determined by Fisher's model of the variance analysis (ANOVA) of the two factorial experiment using a F test for P <0.05 and P <0.01

Fertilization and protection on researched areas

For meliorative fertilization (before planting) as the following fertilizers were used: *NPK 8-26-26, NPK 10-30-20, NPK (SO_3) 5-20-30 S (26) (Florin 1), NPK 7-20-30, NPK 6-18-36 i NPK (MgO) 8-16-24.* In basic fertilization, we apply fertilizer with less nitrogen and more phosphor and potasium, *The programs of protection and fertilization after planating are shown in the tables* 1, 2 and 3.

Table 1. Fertilization and protection in the Mostar area

2015 and 2016	Fertilization	Plant protection
January	NPK (MgO) 8-16-24, 800 kg/ha	/
February	/	Nordox 3x 2kg/ha
March	/	Chorus (200g/ha)+Karate zeon (150ml/ha) and Karate (150ml/ha)+Daconil (2l/ha)
April	NPK 20-20-20	Chorus (200g/ha)+Delan i Dithan+Calypso

During 2015, in the area of Čapljina, there was no need for fertilization, because the soil had enough required elements.

Table 2. Fertilization and protection in the area of Čapljina

2015 and 2016	Fertilization	Plant protection
January	NPK (MgO) 8-16-24, 800 kg/ha	Bordovska čorba
February	/	Chromodin+Confidor+Luna Experience
March	/	Captan 50+Mospilan 20 SP
April

March		Merpan+Kubik Plus+Karate zeon and Mospilan 20 SP+Cadillac 80WP+Akord
April	NPK 30-10-10	Captan 50+Tonus+Dional 500 SC+Dali
May		Affirm+Indar 5 EW+Dithan

Analysis of nectarine fruit

We picked up the fruits from marked threes in all three locations during June and July in 2015 and in 2016. After picking up, fruits were prepared for analysis. We took 50 fruits and we chopped the fruits up and homogenized them, in order to get three average samples of one cultivar. In order to show climate conditions, we used weather measurement units from the Federal hydro meteorological institute in Sarajevo, during both 2015 and 2016. Average monthly temperature was $15,6^0$ C during 2015, in the area of Stolac. In the area of Mostar it

was 16,23^0 C. Average monthly temperature was 15,38^0 C during 2016 (January-July) in the area of Stolac. Monthly average of rainfall was 77,31 l/m^{2,} during 2015 in the area of Stolac. In the area of Mostar, monthly average of rain fall was 110,54 l/m^2. During 2016 (January-July)monthly average of rainfall were 87,74 l/m^2 in the area of Stolac, and 140,72 l/m^2 in the area of Mostar.

Results and discussion

Based on mechanical content of the soil, we defined texture according to USDA classification. The type of soil was mostly sandy loam (table 4.).

Table 4. The soil texture according USDA classification

Location/depth(cm)	sort	Sand %	Loam %	Ash %	Texture
Stolac / 0-30	BT i C 2000*	75	15	10	Sandy loam
Stolac / 30-60	BT i C 2000	73	15	12	Sandy loam
Mostar / 0-30	BT i C 2000	80	10	10	Sandy loam
Mostar / 30-60	BT i C 2000	85	8	7	Sandy loam
Čapljina / 0-30	BT	65	18	17	Loam
Čapljina / 30-60	BT	61	17	21	Loam
Čapljina / 0-30	C 2000	76	13	11	Sandy loam
Čapljina / 30-60	C 2000	76	12	12	Sandy loam
BT= Big Top **C 2000= Caldesi 2000**					

Chemical content of nectarine fruit

The Sort *Big Top* had the highest content of soluble solids and total acids in the area of Stolac (15,14% and 0,72%, respectively). The highest content of ash was in the area of Mostar (1,61%), and the highest content of total sugar was in the area of Čapljina (11,99 %). The highest values were noticed in 2015 (Tables 5 and 6.).

Table 5. Chemical composition of nectarine cultivar Big Top in 2015 and 2016 at locations

Parametar	Soluble solid (%)	ash (%)	total acid (%)	total sugar (%)
2015. Stolac	10,52±13,99	0,01±0,61	0,68±0,72	6,20±7,20

In 2015 we noticed that there was not important difference in the content soluble solid, when we compared all three researched locations (F=3,58; p=0,09). In 2016, the soluble solid in the sort *Big Top* was bigger in the areas of Mostar and Čapljina when we compared it with the area of Stolac (F=29,73; p=0,0008). There was not statistically important difference in the total content of soluble solid in the sort *Big Top* in the area of Stolac, when we compared both years of our research (t=0,05; p=0,96). There was no statistically important difference in total content of dry matter in the sort *Big Top* in the area of Mostar, in both years of our research (t=1,49; p=0,21). Total content of dry matter in the sort *Big Top*, in the area of Čapljina, was statistically higher in 2015 (t=3,5; p=0,025).

Total content of ash in the sort *Big Top* in 2015 was statistically higher in the area of Mostar, when we compared it with areas of Stolac and Čapljina (F=9,02; p=0,015). There was not statistically important difference in total content of ash in the sort *Big Top* in 2016, when we compared all areas of our research (F=1,03; p=0,41). There was not statistically important differences in total content of ash in the sort *Big Top* in the area of Stolac, when we compared both years of our research (t=1,43; p=0,22). Total content of ash in the sort *Big Top*, in the area of Mostar, was statistically higher in 2015 (t=4,34; p=0,012). There was not statistically important difference in total content of ash in the sort *Big Top* in the area of Čapljina, when we compared both years of our research (t=0,84; p=0,44).

The content of total acid in the sort *Big Top* was statistically higher in the area of Stolac and Čapljina, when we compared with the area of Mostar in 2015 (F=17,06; p=0,003). The content of total acid in the sort *Big Top* was statistically higher in the area of Stolac, when we compared it with the area of Mostar and Čapljina in 2015 (F=127,86; p<0,0001). The content of total acid in the sort *Big Top* in the area of Stolac was statistically higher in 2016 (t=4,69; p=0,009). There was not statistically important difference in the content of total acid in the sort *Big Top* in the area of Mostar when we compared with second year of our research (t=0,72; p=0,5). The content of total acid in the sort *Big Top* in the area of Čapljina was statistically higher in 2015 (t=18,24; p=<0,0001).

There was not statistically important difference in the content of total sugars in the sort *Big Top* in 2015, when we compared areas of our research (F=1,018; p=0,41). There was not statistically important difference in the content of total sugar in the sort *Big Top*, in 2016 when we compared the areas of our research (F=2,97; p=0,12). There was not statistically important

difference in the content of total sugar in the sort *Big Top* in the area of Stolac when we compared both years of our research (t=1,53; p=0,2). The content of total sugar in the sort *Big Top* in the area of Mostar was statistically higher in 2016 (t=2,85; p=0,046). The content of total sugar in the sort *Big Top* in the area of Čapljina was statistically higher in 2016 (t=6,09; p=0,0037).

Chemical content of nectarine fruit of the sort *Caldesi 2000*

The sort *Caldesi 2000* had the highest value of dry matter in the area of Stolac (12,92%), the highest value of ash in the area of Mostar (0,66%), the highest content of total acid in the area of Čapljina (1,2%) and the highest content of total sugars in the area of Mostar (10,6%). The highest value of ash was in 2016, and all other values were the highest in 2015. The values of our parameters in both years of our research are shown in the tables number 7 and 8, bellow the text.

Table 7.Chemical composition of nectarine cultivar Caldesi 2000 in 2015 and 2016 at locations

Parametar	Soluble solid (%)	ash (%)	total acid (%)	total sugar (%)
2015. Stolac	11,50±12,92	0,43±0,53	0,58±0,67	5,80±8,60

2016. Čapljina	8,69±8,91	0,27±0,32	0,88±1,20	8,69±8,93
F test Lsd test	t=3,41; p=0,027	t=0,2,31;p=0,08	t=2,83;p=0,047	t=2,03; p=0,11

In 2015, there was not important difference in the content of soluble solids, when we compared researched areas (F=1,47; p=0,3). Total content of dry matter in the sort *Caldesi 2000* was statistically higher in the areas of Mostar and Stolac, when we compared it with the area of Čapljina (F=77,16; p<0,0001). Total content of dry matter in the sort *Caldesi 2000* in the area of Stolac was statistically higher in 2015 (t=5,97; p=0,004). Total content of dry matter in the sort *Caldesi 2000* in the area of Mostar was statistically higher in 2015 (t=12,65; p=0,0002). Total amount of dry matter in the sort *Caldesi 2000* in the area of Čapljina was statistically higher in 2015 (t=3,41; p=0,027).

There was no statistical difference in total content of ash in the sort *Caldesi 2000* in 2015, when we compared three researched locations (F=0,51; p=0,62). Total content of ash in the sort Caldesi 2000 in 2016 was statistically higher in the area of Mostar, when we compared it with two other researched locations (F=5,57; p=0,043). There was not statistically difference in total content of ash in the sort *Caldesi 2000* in the area of Stolac, when we compared both years of our research (t=1,7; p=0,16). There was not statistically important difference in total content of ash in the sort *Caldesi 2000* in the area of Mostar when we compared years of our research (t=0,83; p=0,45). There was not statistically important difference in total content of ash in the sort *Caldesi 2000* in the area of Čapljina, when we compared both years of our research (t=2,31; p=0,08).

Content of total acid in the sort *Caldesi 2000*, in 2015, was statistically higher in the area of Čapljina, when we compared it with researched area of Mostar (F=12,88; p=0,007). Content of total acid in the sort *Caldesi 2000* in 2016 was statistically different in the area of Čapljina, when we compared it with the researched area of Mostar (F=5,89; p=0,038). The content of total acid in the sort *Caldesi 2000* in the area of Stolac was statistically higher in 2016 (t=8,44; p=0,001). The content of total acid in the sort *Caldesi 2000* in the area of Mostar was not statistically different when we compared both years of our research (t=2,24; p=0,08). The content of total acid in the sort *Caldesi 2000* in the area of Čapljina was statistically higher in 2016 (t=2,83; p=0,047).

The content of total sugars in the sort *Caldesi 2000* in 2015 was not statistically different when we compared researched areas (F=0,34; p=0,72). The content of total sugars in the sort *Caldesi 2000* in 2016 was statistically higher in the area of Čapljina, when we compared two other researched locations (F=378,28; p=0,0001). There was no difference in the content of total sugars in the sort *Caldesi 2000* in the area of Stolac, when we compared both years of our research (t=2,39; p=0,07). There was not statistically difference in the content of total sugars in the sort *Caldesi 2000* in the area of Mostar, when we compared both years of our research (t=1,08; p=0,34). There was not statistically important difference in the content of total sugars in the sort *Caldesi 2000* in the area of Čapljina, when we compared both years of our research (t=2,03; p=0,11).

According to Bulatović (1992**)** nectarine fruit contains 4-13% sugar, 0,2-1,5% acid, 0,2-0,8% pectin matter, 0,5% mineral matter (especially K, Ca, and P), 3-20 mg% ascorbic acid (vitamin C), while the content of other vitamins is at about 1 mg%. Mišić P.D. (1994) highlights that nectarine fruit contains water (87%) and dry matter (13%), and that is organic matter (carbohydrates, organic acid, proteins, lipids and many others), and inorganic matter and biogenic elements. According to Ninkovski (1984) structure of sugars in nectarine fruits is following: the highest content of saccharine is at about 7,34% from the whole content of fruit, in the 100 g, there is 2,15 g of glucose, and there is the lowest content of fructose (fruit sugar), there is at about 0,44 g in the whole content of 100 g of nectarines mesocarp. Wills et al. (1983) highlight that in nectarine fruit, the most important is saccharine (54-75%), fructose (3-25%), glucose (9-21%) and sorbitol (4-11%) in the whole content of sugars. According to Byrne et al.(1991) the most common organic acid in fruits are malic acid, citric acid and quinolic acid. According to Wills et al.(1983) the content of organic acid is eight times lower

than the content of sugars. Even if the content of acids is not that high, they are important for the taste of fruit. Ninkovski (1984) highlights that citric acid and malic acid are dominant in nectarines fruit, and after them there is ant acid and valeric acid. According to Colarič et al. 2004) there is content of total sugar in the nectarine sort *Spring red* from 67,50 g/kg, and content of total acid from 12,55 g/kg. Content of total sugar in the sort *Venus* was 91,96 g/kg, and content of total acid was 11,50 g/kg. In his research of peach (*Prunus persica L.*), Bakić (2016) told that total content of acid was 0,32- 1,07% in 2012 and from 0,40% to 1,02%, and content of total sugars from 11,10-18,84%.

Conclusion

At the location of Mostar, the cultivar Caldesi 2000 has been proven to be better in terms of the higher content of total acids and total sugars. Cultivar Big Top at Stolac had a higher soluble solids and higher total sugars content.

At the location of Čapljina, the Caldesi 2000 has a higher content of total acids, and the Big Top variety has a higher content of soluble solids.

It can be concluded that both cultivars have a good chemical composition and no major deviations from similar investigations. As far as the location is concerned, the Caldesi 2000 cultivar is more suitable for the Mostar area. At locations Stolac and Čapljina both cultivars are suitable for breeding.

Abstract

Tomato is the second most consumed vegetable in the EU and a major dietary source of many nutrients, vitamins and antioxidants.Tomato is a rich source of lycopene, β-carotene, α-tocopherol, phenolic components, the necessary minerals, primarily potassium and carboxylic acids including ascorbic, citric, maleic, fumaric and oxalic in human diet. Demand for organic tomatoes is increasing due to its nutritious value.Lycopene concentration of in tomato samples was determined by spectrophotometric method. The results showed that the lycopene content of in the Matias hybrid ranged between 5.42 mg/100g (conventional production) to 5.55 mg/100g (integrated production).The lycopene content in the Sakura hybrid ranged in between 6.30 mg/100g (conventional production) to 6.56 mg/100g (integrated production).The results obtained showed significant statistical differences in lycopene content of Matias varieties which was higher on the ones grown at the location Pocitelj brdo(6.17mg/100g) compared to Butmir(5.48mg/100g). Variety Sakura also had significantly higher values determinetaed the location Pocitelj brdo(6.80 mg/100g) compared to the same variety at the location Butmir(6.43mg/100g).

Keywords: *Tomato,Lycopene, Production systems, Agro-ecological conditions.*

Introduction

In recent years there has been a dramatic increase in the availability of scientific publications about the role of fruits and vegetables in human health. Tomato is the second most consumed vegetable in the EU and a major dietary source of many nutrients, vitamins and antioxidants. Tomato is recommended for strengthening the body defense system but also for good diet because it is nutritious and low in calories. Over the last decade lycopene has been singled out as a significant factor in the prevention of chronic diseases.

Much attention has been focused on oxidative stress-induced cellular damage which is recognized as leading factor for of chronic diseases. Antioxidants play an important role in reducing the harmful effects of oxidative stress. Free radicals can bee removed from the body by using high amounts of lycopene. Tomatoeisrich in this important antioxidant due to its luxurious red colour. Our body cannot produce lycopene. Except in tomato, lycopen is found in the watermelon, pink grapefruit and papaya.

Numerous epidemiological studies have shown that dietary intake of food rich in lycopene can reduce the incidence of some types of cancer, including prostate, breast, lung, and colon cancer, coronary artery disease, hyperglycemia, cataracts and macular degeneration. (Lopez *et al*., 2007;Böhm, 2011).Beside this red coloured carotenoid, other ingredients of tomatoes (e.g. ascorbic acid, folic acid, phenolic compounds) may also be responsible for beneficial effects (Böhm, 2011).

Tomato is a rich source of lycopene, β-carotene, α-tocopherol, phenolic components, the necessary minerals, primarily potassium and carboxylic acids including ascorbic, citric,

maleic, fumaric and oxalic in human diet. Some of these tomatoes compounds have antioxidant activity (Gastélum-Barrios *et al*., 2011.)

Some of these elements such as sodium, potassium, magnesium, copper, zinc and iodine in tomato can reduce the risk of cardiovascular disease, and the organic acid contributes to the securing of the base of ballast acid in the body. Tomato has an effectiveinfluence on the human health. Consumption of tomatoesand its products (ketchup, pasta) prevents development of tumors in the digestive tract and prostate cancer (Caris-Veyrat *et al*., 2004).

Today, tomato is the part of prevention as well as help in treating the most common diseases of modern humanity. This has caused increased interest of consumers for organically cultivated tomatoes, including those produced in greenhouses. The task of producers and manufactures is to provide sufficient quantities of healthy and safe tomatoeproduct with complete information for the consumers about when, where and how it is produced. According to Periago(2011) the results indicate that lycopene content depends on the maturation stage of tomatoes, showing the highest amounts can be obtained in full red stage.

After a 10-year research of the chemical composition of tomatoes from the organic production compared with the ones grown of the integral and conventional production systems Mitchell (2007) came to the conclusion that organic tomatoes contained twice as many antioxidants-flavonoid and significantly more lycopene (quercetin, kamferol and naringenin) that help in the prevention of high blood pressure and also reduce the likelihood of heart disease and stroke. These researchers claim that flavonoids may help in curingsome forms of cancer and dementia. If in the 3-weekly diet 30 g of ketchup or 400 ml of tomato juice a day are included, total cholesterol levels reduces by 5.9%, while the level of LDL decreases by 12.9%.

Tomato is an excellent product in the improvement of health because, in addition to the abovementioned facts, it also contains a balanced mix of elements (K, Fe) and antioxidants including vitamins C and E, lycopene, β-carotene, lutein and flavonoids. Demand for organic tomatoes is increasing, mainly because it contains less nitrate and nitrite than the ones grown under integrated and conventional production systems. Additionally, consumers receive a product free of pesticides, potentially better taste, not genetically modified and are often produced in an area that is very close to the consumers.

Material and methods

In order to evaluate the influence of different production systems (organic, integrated and conventional) and the different agro-ecological conditions on the lycopene content a two years trial was carried out . The trial was conducted under conditions of moderate continental climate Butmir-Sarajevo (altitude of 550m) and the terms of sub-Mediterranean climate site Pocitelj - Čapljina (altitude 75m).

The experiments were separately carried out for organic, integrated and conventional production. All production systems include a common method for the production of tomatoes in the open (block system). In the conventional production system,we used mineral fertilizer NPK (100 kg N, 80kg P_2O_5,100 kg K_2O per hectare. In this system we used chemical for plant protection. For organic production we used organic fertilizer (30 tons per hectare). Diseases and insects were controlled by biological methods. For integral production, we used combined fertilizer and protection measures.

The experiment was set by random order in five repetitions. The size of the experiments parcel was 4.2 m^2.The distance between the plant was 80x50cm.

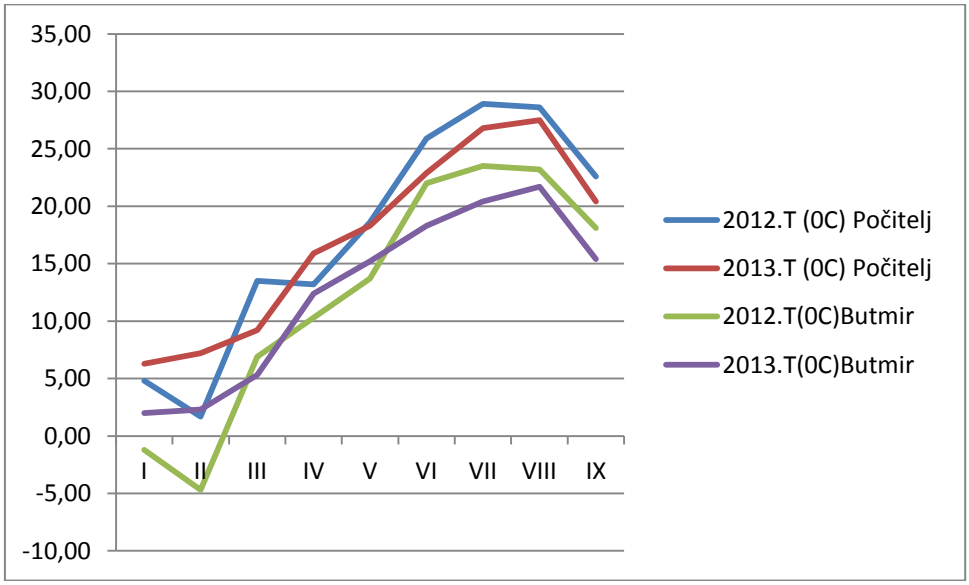
The concentration of lycopene on a sample of 5 plants of each variant experiment was determined by spectrophotometric method in the laboratory of the Federal Institute for Agriculture Sarajevo.In order to obtain information on the concentration of lycopene in a sample, provided is a spectrophotometric analysis of a sample of pure lycopene (standards)

(Shi *at all*.,1999., Shi and Le Maguer, 2000., Lovrić, 1970., Mencarelli and Saltveit, 1988., Tan and Soderstrom, 1988.).

Statistical analysis of the results was determined by analysis of variance. Rating particular significance studied factors and their relationship tested based on the LSD test for significance level of 1% and 5%. Processing of the data obtained in the research is presented in tables and graphs.

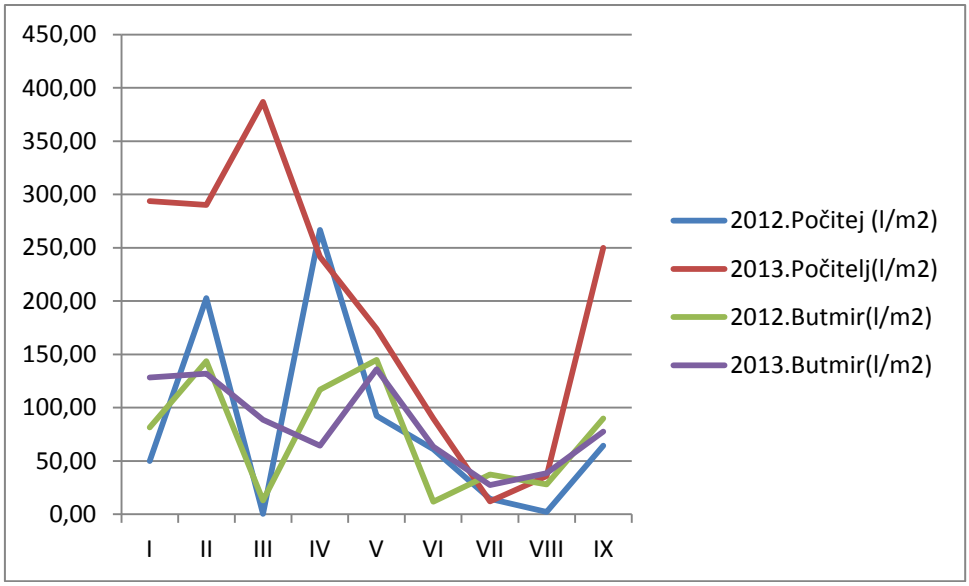
Climatic characteristics

The average monthly temperatures at Butmir in 2012 were the highest in July 23.5(^{0}C), and the lowest in February was -4.7(^{0}C) . During 2013, the average monthly temperature at the Butmira site was highest in August, 21.7(^{0}C), and the lowest in January 2.0(^{0}C). At the locality of Počitelj, the average monthly temperature in 2012 was the highest in July 28.9(^{0}C) and the lowest in February 1.7(^{0}C). During 2013, the average monthly temperature at the Počitelj site was the highest in August, 27.5(^{0}C) and the lowest in January 3.6(^{0}C). (graph 1)



Graph1.Average monthly air temperatures(^{0}C) during 2012-2013

The highest amount of rainfall in the Butmir site in 2012 was in May (144.9 l/m^2) and the lowest in March (13.0 l/m^2). At the site of Počitelj, the highest rainfall sum in 2012 was in April (266.6 l/m^2), the lowest in March (0.3 l/m^2). In 2013, the largest amount of rainfall in Butmir was in May (136.0 l/m^2), while the lowest was in July (27.3 l/m^2). At the site of Počitelj, the highest precipitation peak in 2013 was in March (386.8 l/m^2) and the lowest in August (35.7 l/m^2). (graph 2)



Graph 2.Monthly precipitations (l/m^2) during 2012-2013

Results and Discussion

The content of lycopene in 2012 in different production systems (organic, integrated and conventional) in a variety Matias had different values.The highest content of lycopene in varieties Matias in Butmir was in integral(5.41 mg/100g), then the organic(5.40mg/100g) and conventional production(5.06mg/100g). So,in an integral and organic system of production is expressed statistically significant difference, while the concept inrelation to conventional production showed significant statistical differences.

The highest contentof lycopene in variety Sakura was in the conventional system(6.32 mg/100 g), then the integral(6.30 mg/100g) and organic production(6.28 mg/100g). Statistically significant differences were revealed in production systems at variety Sakura. However, a significant difference between the varieties Matias and Sakura were significantly manifested. Significantly higher yields of lycopene were found in the variety Sakura in all three production systems. At the location of Pocitelj lycopene contentin 2012 in different production systems (organic,integrated and conventional) was also different.The content of lycopene in varieties Matias was the highest in the organic(6.15mg/100g), then the integral(6.06 mg/100g) and conventional production(5.98 mg/100g). Matias varieties in different production systems, no statistically significant differences. The highest content of lycopene in variety Sakura was in the organic system (6.41 mg/100 g), followed by conventional (6.32 mg/100g) and integrated production (6.32 mg/100g). Statistically significant differences were revealed in production systems at variety Sakura, nor have demonstrated a statistically significant difference compared to the sites of production.

Table 1. The content of lycopene in 2012 from different cultivation systems and different localities (mg/100g)

Variant	Location Butmir		Location Počitelj	
	Matias F_1	Sakura F_1	Matias F_1	Sakura F_1
Organic prod.	5.40	6.28**	6.15	6.41
Integrated prod.	5.41	6.30**	6.06	6.31
Convent. prod.	5.06	6.32**	5.98	6.32
LSD 5%	0.09		3.3	
LSD 1%	0.13		3.6	

The content of lycopene in 2013 in different production systems (organic, integrated and conventional production) at variety Matiashad different values.The highest content of lycopene in varieties Matias in Butmir was conventional (5.78mg/100g), then the integral(5.70mg/100g) and organic production(5.57 mg/100g). The demonstrated statistically significant differences in conventional and integratedin relation to organic production.No statistically significant differences between conventional and integrated production.
Variety Sakura had the highest content of lycopene in the integral(6.82 mg/100g), then the organic (6.54 mg/100g) and conventional production (6.29mg/100g). Statistically significan tdifferences have been revealed in the integral over conventional production and statistically significant differences in relation to organic production. Variety Sakura exhibited a significantly statistical difference in all production systems in Butmir in relation to the other studied cultivars. Content of lycopene(2013) on the location Pocitelj in different production systems (organic, integrated and conventional production) was different.Matias variety in different production systems showed no statistically significant differences.The highest content of lycopene in variety Sakura was in the integral(7.28 mg/100 g), followed by conventional(7.26 mg/100g) and organic
production(7.22 mg/100g).Recently,differences and variations in the lycopene content in tomato grown in organic systems versus the conventional way of farming was studied (Riahi *et al*. ,2009.,Barrios – Masias *et al*.,2011., Riahi and Hdider 2013)

Table 2. The content of lycopenein 2013 from different cultivation systems and different localities (mg/100g)

Variant	Location Butmir		Location Počitelj	
	Matias F_1	Sakura F_1	Matias F_1	Sakura F_1
Organic prod.	5.57	6.54*	6.33	7.22*
Integrated prod.	5.70	6.82*	6.23	7.28*
Convent. prod.	5.78	6.37	6.29	7.26*
LSD 5%	0.71		0.89	
LSD 1%	1.01		1.26	

Table 3 shows the influence of locality on lycopene content in tomato fruits Significant statistical differences in the content of lycopene of varieties Matias are higher at the location Pocitelj(6.17mg/100g) compared to Butmir(5.48mg/100g).
Variety Sakura also significantly higher values determined at the location Pocitelj(6.80 mg/100g) compared to the same variety at the location Butmir(6.43mg/100g). Results of the previous researches proved that the concentration of lycopene depends on the vegetation season, location, variety and degree of ripeness. Besides genetic factors, the content varies depending on crop management, especially depending on the input of nutrients into the soil (nitrogen, phosphorus, potassium and calcium) and temperature variations (Garcia and Barrett, 2006., Dumas *et al*., 2003., Adeniyi and Ademoyegun, 2012). The content of lycopene is genetically determined, but is strongly influenced by environmental conditions.

Table3.The effect of locationon the content of lycopene in tomato fruits (mg/100g)

Content of lycopene	Location Butmir		Location Počitelj	
	Matias F_1	Sakura F_1	Matias F_1	Sakura F_1
	5.48	6.43	6.17**	6.80**
LSD 5%	0.23			
LSD 1%	0.29			

Conclusions

The analysis of the two-year results determined the significant influence of the site, ie the agroecological conditions on the value of lycopene:

At the location Butmir in 2012, the highest content of lycopene in the Matias F_1 was in integral production (5.41 mg / 100g), and in the Sakura F_1 in conventional production (6.32 mg / 100g). At the location Počitelj in the same year, the highest content of lycopene was recorded in organic production in both varieties examined.

In the second study year (2013) at the location Butmir, the highest content of lycopene in the Matias F_1 was in conventional production (5.78 mg / 100g), and in the Sakura F_1 in integral production (6.82 mg / 100g). In the same year, at the location Počitelj, the highest content of lycopene in the Matias F_1 was in organic production (6.33 mg / 100g), and in the Sakura F_1 in integral production (7.28 mg / 100g).

Abstract

Commercial production of tomato is based on the use of transplants with a substrate lump around the root, which is also the most expensive transplant production method. In order to explore the possibility of growing transplants using a more cost-effective, innovative hydroponic technology applicable on family farms, a two-factor trial was set according to the method of completely randomized design (CRD). The research factors, term of putting the containers on nutrient solution, and substrate volume of a seeding place, were analysed through three levels. The transplants were grown on substrates of individual seeding place volumes of 27, 37 and 47 ml in containers placed on nutrient solution immediately after sowing, after previous germination and when the plants were in the stage of development of cotyledon leaves. For each type of container, transplants were also grown using the classic method, which was the control variant. The percentage of well-developed tomato transplants was greater for the cultivation on nutrient solution in the containers with previously germinated seeds in comparison with conventionally grown transplants. Also, the transplants grown on nutrient solution had higher values of analysed growth parameters in comparison with classic growing. Each of the tested variants had a highly significant effect on stalk length, diameter and the number of leaves of tomato transplants, while a highly significant interaction of individual variants was also established for stalk length. The research results indicated that high-quality tomato transplants could be produced using the growing technology in floating containers on nutrient solution, which would certainly help in reduction of transplant production costs for smaller commercial vegetable producers.

Keywords: *transplants, tomato, floating containers, nutrient solution*

Introduction

Modern production of transplants is carried out in greenhouses; however, more than 70% of rural producers still produce transplants in hot plots (Parađiković and Kraljičak, 2008). Limitations in the possibilities of high-quality soil disinfection are a big problem in this growing method, which is why a significant part of transplants is ruined by diseases, weediness and manual weeding increase production costs. Commercial production of tomato is based on the use of transplants with a substrate lump around the root, which represent a significant cost item. It is important to choose an appropriate size of individual cell in the container because there is a direct relationship between it and development of transplants (Leskovar, 2001). The size of the container is more important than the type of container (Splittstoesser, 2004) where the volume of substrate is a key factor influencing not only growth but also overall yield and quality (Jankauskienė and Brazaitytė, 2009).

Most producers on small family farms do not have adequate equipment to control temperature and application of irrigation, which puts the production of transplants at risk. Considering these disadvantages, a floating system can be applied as a simpler method for production of transplants. The new method of growing vegetable transplants has been discovered by using hydroponic floating system in the tobacco industry. Interpreting the achievements in

production of tobacco transplants, Carrasco and Izquierdo (2005) gave recommendations for production of vegetable transplants in the floating system. The conventional production of transplants is labour intensive, while cultivation in a floating system can be a less labour-intensive alternative method for the production of transplants of melons (Bilalis *et al.*, 2008), or tomatoes and lettuce, where watering is not necessary (Bilalis *et al.*, 2009). The growth of transplants on nutrient solution is faster than in classic growing technology, and therefore for the same planned planting period, growing of transplants can begin a week later than in classic growing technology (Matotan *et al.*, 2007). Wyatt (1998) was among the first to write about the advantages of growing tomato transplants in the floating system as a sustainable alternative production method. In the floating system, it was possible to produce high-quality tomato transplants (Rideout, 2004), that had higher values of the analysed properties in comparison with those that were grown conventionally, according to Enciso Garay *et al.* (2015).

The objective of the research was to determine the optimum term for putting containers on the nutrient solution after sowing and optimum volume of substrate for growing tomato transplants in the floating system.

Material and Methods

In order to establish the possibility of producing tomato transplants in floating containers on nutrient solution using a technology adapted to family farms in unheated greenhouses on cv. Belle F1, a two-factor trial was set according to the method of completely randomized design (CRD). The main factor, term of putting the containers on nutrient solution (A) was observed through three steps: A1-directly placing the containers on nutrient solution immediately after sowing, A2-placing the containers on nutrient solution after previous germination of seeds, and A3-placing the containers on nutrient solution in the stage of developed cotyledon leaves. The second factor, seeding place substrate volume, or the most favourable number of seeding places in a container (B) also had three steps: B1-23 ml (160 seeding places), B2-37 ml (104 seeding places) and B3-47 ml (84 seeding places). Polystyrene containers (50 x 33 cm) were filled with substrate for production of vegetable transplants Potgrond H (Klasmann). Sixteen containers of each variant were sown, which is a total of 48 containers. One container of each variant was left in the greenhouse where it was further grown in the usual conventional way and was used for comparison of growth as the control variant. Fifteen containers of each variant were put on nutrient solution, occupying an area of 8 m^2 in a reservoir with total area of 22.5 m^2 and water volume 3 m^3. The nutrient solution was prepared using the water-soluble fertilizer Kristalon green special (NPK 18:18:18) in the amount of 1 kg/m^3. Because of evaporation of the solution from the reservoir, fresh water was periodically added trying to keep the EC value constant at a level of 1.5 mS/cm and pH value 5.8-6.3. For the amount of water in the reservoir, 300 ml of Previcur 607 SL fungicide was preventively added. In the fifth week after sowing, on a sample of ten plants of each variant from one container intended for analysis, transplant development parameters were measured: transplant stalk length (cm), transplant stalk diameter immediately below the cotyledon leaves (mm) and counting of developed leaves. The percentage of well-developed transplants suitable for replanting was also established. The research data obtained for growth parameters of the transplants grown on nutrient solution were statistically treated by variance analysis (ANOVA), while the LSD test examined the differences between mean values with the significance level p 0.01. The data were processed using the statistical program SP SS 13 (*Statistical Package for the Social Sciences*).

Results and Discussion

The variants grown on nutrient solution had higher values for the analysed properties compared to conventionally grown transplants (Table 1).

High percentages of well-developed tomato transplants were determined, 96.4%-99.1%, thus achieving one of the preconditions for successful production. The highest percentage of well-developed transplants suitable for replanting was obtained in the containers placed on nutrient solution when transplants had developed cotyledon leaves, while the lowest percentage was in the containers placed immediately after sowing, the value of which was at the level of the control variant. Also, high percentages of tomato seed germination, 89.0%-93.0% in a floating system were reported by Bilalis *et al.* (2009).

In cultivation on nutrient solution, taller transplants were measured, which also had greater stalk diameter and number of leaves in comparison with conventionally grown transplants. Similarly, Wyatt (1998); Verdial *et al.* (1999); Rideout (2004); Enciso Garay *et al.* (2015) showed that tomato transplants grown in floating system were higher and had greater stalk diameter than conventionally grown transplants (Rideout and Overstreet, 2003; Enciso Garay *et al.*, 2015).

Table 1. Development of transplants grown on nutrient solution and with classic technology

Seeding place substrate volume, B (ml)	Term of putting the containers on nutrient solution, A			Control
	After sowing	After germination	In cotyledon stage	
The percentage of well-developed transplants (%)				
23	97.5	98.6	99.4	98.1
37	95.9	98.3	98.6	97.1
47	95.8	97.3	99.4	95.2
Average	96.4	98.1	99.1	96.8
Transplant height (cm)				
23	24.84	26.27	34.80	10.62
37	24.68	18.63	35.34	13.24
47	22.21	19.81	26.65	13.49
Average	23.91	21.57	32.26	12.45
Diameter (mm)				
23	4.27	3.72	4.30	2.50
37	4.34	3.98	4.29	3.21
47	4.08	3.93	4.89	3.27
Average	4.23	3.88	4.49	2.99
Number of leaves				
23	4.10	4.10	4.50	3.00
37	4.20	4.10	4.50	3.10
47	4.10	4.20	5.20	3.00
Average	4.13	4.13	4.73	3.03

Each of the tested variants had a highly significant effect on tomato transplant height, while only the factor term of putting the containers on nutrient solution showed a highly significant effect on stalk diameter and the number of leaves (Table 2).

Transplants in the containers placed on nutrient solution when plants had developed cotyledon leaves were highly significantly highest, while those in the containers placed on nutrient

solution immediately after sowing were lowest. Stalk elongation occurred in containers with larger numbers of seeding places, and significantly higher transplants were on substrate with smallest seeding place volume. Excessive elongation of stalks is a potential problem in both conventional and floating tomato transplant production system (Rideout and Overstreet, 2003). Tomato transplants in the containers placed on nutrient solution in cotyledon stage had the largest diameter, which is at the same significance level with the variant where containers were placed immediately after sowing. Also the significantly largest number of leaves was in the containers placed on nutrient solution when the transplants were in the cotyledon stage. Although the differences in stalk diameter and number of leaves conditioned by substrate volume were not statistically significant, the highest average values were on the largest substrate volume of individual seeding place and decreased with decreasing substrate volume. Similar reports were made by Weston and Zandstra (1986), where tomato transplants grown in the containers with smaller individual seeding place volume developed a smaller number of leaves, and Dumičić *et al.* (2016), who explained that the number of leaves was linearly decreasing under the influence of smaller pot volume, while stalk diameter was not affected by pot volume.

Table 2. Influence of individual factors on measured properties of tomato transplants

Term of putting the containers on nutrient solution, A	Transplant height (cm)	Stalk diameter (mm)	Number of leaves
A1	23.91 b	4.23 ab	4.13 b
A2	21.57 c	3.88 b	4.13 b
A3	**32.26 a**	**4.49 a**	**4.73 a**
Average	25.91	4.20	4.33
$LSD_{p=5\%}$	1.13	0.32	0.29
$LSD_{p=1\%}$	1.50	0.43	0.38
Seeding place substrate volume, B (ml)	Transplant height (cm)	Stalk diameter (mm)	Number of leaves
B1	**28.64 a**	4.10 a	4.23 a
B2	26.22 b	4.20 a	4.27 a
B3	22.89 c	4.30 a	4.50 a
Average	25.91	4.20	4.33
$LSD_{p=5\%}$	1.13	n.s.	n.s.
$LSD_{p=1\%}$	1.50	n.s.	n.s.

Interaction of individual factors had a highly significant effect only on the property transplant height (Table 3).

The maximum transplant height, 35.34 cm, was obtained in the containers placed on nutrient solution when transplants had developed cotyledon leaves on substrate of medium seeding place volume and highly significantly differed from average values of other combinations, with the exception of the combination of the same term of putting the containers on nutrient solution and the smallest seeding place substrate volume, 34.80 cm, from which it did not significantly differ. In tomato transplants, with application of the sub-fertirrigation technique in the stage of fully developed cotyledons, Dumičić *et al.* (2016) explained from presented interactions that transplant height was more influenced by pot volume, as the height was mainly increasing with its decrease, which is consistent with the results of this research.

As a result of interaction of individual factors, the highest values for the properties stalk diameter, 4.89 mm, and number of leaves, 5.20, were not significantly different from average values of other combinations. Thus, with interaction of individual factors, although the differences were not significant, the largest diameter and number of leaves were established in the containers placed on nutrient solution when transplants had developed cotyledon leaves on substrate of the largest seeding place volume.

Table 3. Influence of interaction of individual factors on measured properties of tomato transplants

Term of putting the containers on nutrient solution (A)	Transplant height (cm)			Stalk diameter (mm)			Number of leaves		
	Seeding place substrate volume (B)								
	B1	B2	B3	B1	B2	B3	B1	B2	B3
A1	24.84	24.68	22.21	4.27	4.34	4.08	4.10	4.20	4.10
A2	26.27	18.63	19.81	3.72	3.98	3.93	4.10	4.10	4.20
A3	34.80	**35.34**	26.65	4.30	4.29	4.89	4.50	4.50	5.20
LSD $_{p=5\%}$	1.96			n.s.			n.s.		
LSD $_{p=1\%}$	2.59			n.s.			n.s.		

Conclusions

Using the growing technology in floating containers on nutrient solution, it was possible to cultivate high-quality tomato transplants that had higher values of development parameters in comparison with conventionally grown transplants. The percentage of well-developed transplants was higher for cultivation on nutrient solution in containers placed on nutrient solution with previously germinated seeds and with plants in cotyledon stage in comparison with conventionally grown transplants. Height, stalk diameter and the number of leaves of transplants were significantly greater when containers with plants in the cotyledon stage were placed on nutrient solution. When growing transplants on substrate with smaller volume of individual seeding place, transplants were less developed and stalks were elongated.

In addition to reduction of costs on account of easier system installation and maintenance of water and nutrition regimen, these results indicate the applicability of tomato transplant growing technology on nutrient solution for smaller commercial producers.

Abstract

Lettuce (*Lactuca sativa L.*) is a highly valued vegetable in human nutrition not only for its richness in minerals and vitamins but also for the fact that nowadays it is produced all year round, and consumed fresh so that all the ingredients stay intact. Taking into consideration the fact that lettuce is the most commonly grown vegetable in the world, there is a large selection of varieties. The aim of the research was to distinguish and to measure the differences in productive characteristics and contents of nitrates in the there the most planted lettuce varieties in greenhouses of Bosnia and Herzegovina. The research was implemented during the growing season 2016/2017. in greenhouse sized 200 m^2. Lettuce was planted 7.12.2017. The research was conducted on lettuce samples of the types butterhead (Shangore and Nantes) and batavia (Funly). At technological maturity lettuce samples were collected for analyses.
The productive parameters which showed significant differences between varieties are average mass of the formed head (0,261-0,372 kg/head) and yield (3,56-5,948 kg/m^2). On the other side, a significant influence of variety was not proved statistically in the case of nitrates content in lettuce heads. The contents of nitrates were ranged (1200 to 2500 mg/kg).

Key words: *Lettuce, Variety, Mass of the formed head, Yield, Nitrates content*

Introduction

Lettuce is an important dietary leafy vegetable that is primarily consumed fresh or in salad mixes. It is one of the most important vegetables grown in greenhouse especially in winter period with or without heating system. Green leafy vegetables contain the highest nitrate levels, and lettuce is classified as having very high nitrate concentrations accumulate in edible parts. The acumulation of nitrates is a consequence excessive adoption of the nitrates from soil or insufficient reduction in the plant. Nitrates themselves have relatively low toxicity to the human body, but their metabolites and reaction products nitrits and nitrosamines in the digestive tract can pose health concerns. The first international risk assessment related to the introduction of nitrates and nitrites was made by JECFA in 1961 (FAO / WHO, 1962). They examined the toxicological impact of nitrates and nitrits, and they established in 1990. Acceptable daily intake, ADI from 0 to 3,7 mg/kg body weight (EC, 1992). Nitrates are mainly created and introduced endogenously (Lundberg et all., 2004 and 2008). The content of nitrates is dependent on growing conditions: temperature, intensity of light, seasons, nutrition and means of fertilization, cultivation methods and, last but not least, variety (Dich et al., 1996). Control of nitrate content in plant products is systematically carried out in developed countries of the world, and there are established guidelines for monitoring the quality of agricultural products in the EU. The maximum allowable quantity of nitrates in the lettuce was determined by the Rule book of the maximum allowed quantities for certain food contaminants (Official Gazette of BiH, No. 68, page 39). If the harvest of lettuce grown in open air is performed in the period from 01.10. - 31.03. it amounts to 4000 mg kg^{-1} of fresh weight, while for a lettuce grown in a protected area it amounts to 5000 mg

kg^{-1}. For harvest carried out in the period 01.04. - 30.09. in a protected area, the maximum permitted nitrate content is 4000 mg kg^{-1} of fresh weight. If in the same period the lettuce is grown on the open field, the value of the maximum allowed quantity of nitrate is 3000 mg kg^{-1} of fresh weight. Therefore, the objective of this paper is to determine the effect of the variety on the nitrates content and on the yield performance of lettuce.

Material and Methods

The research was conducted during the period of October 2016 to May 2018 in greenhouse without heating system, in region of Srebrenik. The experiments were set in a randomized block design with three replications with varieties of Butterhead (Shangore F1 and Nansen) and Iceberg / Crisphead (Funly F1). The lettuce was produced from seedlings planted on black PE foil, at a spacing of 25x25 cm. Each block contained 16 lettuce plants. During the production cycle, all standard measures for the cultivation of lettuce on foil were employed including covering of plants by agrotextile.

The analyses of nutrients contents were performed after harvest. A mixed sample was done from randomly selected thirty plants of each repetition.

- Lettuce plant diameter was measured only from the part of the plant that we can eat.
- Lettuce heads were weighed on digital scales. Average weight of heads and yield per square meter were calculated from the measured values.
- The content of nitraes was determined using the by colometric quick test procedure HACH. Fresh leaves were chopped and pressed in hydraulic press to express plant sap. For the HACH kit, diluted sap was placed in two viewing tubes (suppled with kit). One tube was placed in its slot in a hand-held comparator. The contents of one reagent powder container were emptied into the second viewing tube and the solution was mixed by shoking for 1 min. After mixing, the second viewing tube was placed in its slot in the comparator. The color disk on the computer was rolated until the color on the wheel matched the color in the tube with reagent. The resulting nitrate concetracion was read from comparator.
- Average values of the parameters in the study were statistically processed with computer, using software Excel. Data analysis was performed using the Analysis of Variance (ANOVA) and Least Significant Differences (LSD).

Results and Discussion

Table 1 shows effect of varieties on productive characteristics of lettuce. The productive parameters which showed significant differences between sorts are average mass of the formed head and yield.

Table 1. Sorts effect on leaf yield and yield contributing characteristics of the lettuce.

Parameters / Varieties	Leaf yield plant (kg)	Waste leaves (%)	Yield kg/m2
Shangore	0.371 ± 0.123^{a}	8.337 ± 3.60^{b}	5.95 ± 0.123^{a}
Nansen	0.241 ± 0.781^{b}	9.047 ± 6.50^{b}	3.86 ± 0.781^{b}
Funly	0.261 ± 0.087^{b}	9.192 ± 3.70^{b}	4.18 ± 0.087^{b}

* Values marked by different small letters are statistically significantly different n <0.05.

The highest leaf yield per plant was obtained from Shangore (0,37 kg) and lowest was found in Nansen (0,24 kg). According research Castoldi et al. (2014) the average mass of educated heads was greater than 200 g, which coincides with the results of this research. In contrast, there are studies where the average mass of the head was significantly lower (Valšíková and Viteková, 2006; Todorović et al., 2012).

The highest leaf yield per square meter had Shangore (5,95 kg), which was statistically different from other varieties. The lowest yield (3,86 kg/ m^2) was obtained in the Nansen variety, which also had the smallest head. The factors such as cultivation season, weather conditions and cultivar influenced the formation of phytomass of leaf rosette, which affected its total weight. Koudela and Petříková (2008) also reported that the spread diameter, average weight of heads and yield are affected by variety. These results correspond to the results listed by (Custic et al., 1994; Todorović et al., 2012).

In order to determine whether there was a statistically significant difference in the mass weight between the examined varieties, a variance analysis was performed and a significant F value was established. The Lsd-test was used to test the significance of the differences in the environment.

The nitrates content ranged from 1030 to 2500 mg per kg (Figure 1), it shows that the lettuce produced in this research had a significantly lower level of nitrate than the upper limit allowed by the Ordinance of BiH (Official Gazette of BiH, No. 68, page 39).

Figure 1. Nitrate concentrations in fresh lettuce mass (mg NO_3 kg^{-1} of a fresh mass)

The highest content of nitrates (2500 mg NO_3 kg^{-1} of a fresh mass) was found in Nansen and the lowest in Shangore (1030 mg NO_3 kg^{-1} of a fresh mass). The differences among varieties were not statistically significant. The content of nitrate reported by Prodanović et al., 2001; Toth, 2006; Čustić et al.,1994 is similar to the results of our experiments

Conclusion

According to the study of the influence of sort on the average mass, yiel and nitrate content in a fresh lettuce mass, we can conclude following:

Average mass of lettuce head and hence yield of lettuce varied significantly between different varieties. The best values of all observed pruducitve parameters were determined in Shangore. Leaf yield per plant and yiled depended of sortsand ranged from 0,24 to 0,37 kg.

On the other side, there were no significant differences in nitrates contents. The lowest nitrate concentration in a technological ripeness has been recorded from Shangore (1030 mg NO_3 kg^{-1} of a fresh mass) and the highest has been recored from Nansen (2500 mg NO_3 kg^{-1} of a fresh mass).The tested varieties in protected areas can be successfully grown during the winter period.

NITROGEN DYNAMICS IN THE SOIL - PLANT SYSTEM UNDER DEFICIT IRRIGATION STRATEGIES IN POTATOES

Mirjana JOVOVIC[1]*, Zorica JOVANOVIC[2], Radmila STIKIC[2]

Abstract

Experiments were conducted in the open field with silty-clay soil to study the effects of subsurface drip irrigation treatments, full irrigation (FI), regulated deficit irrigation (RDI) and partial root zone drying (PRD), on nitrogen (N) dynamics in the soil – plant system of potatoes. FI plants received 100% of evaporative demands, while RDI and PRD plants, in static approach in 2007, received 70% of water of FI and dynamic approach in 2008 where the reduction of water for PRD irrigation from 70 to 50% was done in the stage of tuber ripening. By four or five harvests during the season we measured N content of leaves, stems and tubers were followed. Results showed, in both years, that N concentration in leaves and stems was progressively reduced during the growing season until final harvest when the lowest values were found in all irrigation treatments. In both years the PRD treatments resulted in the increase N in potato tubers.At final harvest N content was by 16% significantly higher in PRD than in FI plants in 2008. Results for N plant content indicated that PRD treatment could improve allocation of N from shoot to tuber at final harvest, although soil N data pointed out that PRD treatment could be beneficial from the point of increasing N - use efficiency.

Keywords: *Nitrogen content, Solanum tuberosum* L., *Partial root drying (PRD), Regulated deficit irrigation (RDI).*

Introduction

Potato (*Solanum tuberosum* L.) rate fourth in production volume among the world various agricultural products after wheat, rice and corn (FAO, 1995). Potato is grown in different agroecological regions but it is the best adapted to temperate climate and frost – free seasons. It is also sensitive to heat and drought stresses and predictions are that future climate change will significantly affect potato production worldwide Haverkort (2008). As a shallow –rooted crop irrigation is crucial for growing potato plants even in humid areas. A high level of nitrogen (N) is recommended for potato cropping (Darwish et al., 2003) to ensure acceptable yield.

As fresh water resources become scarce, it is difficult to irrigate crops to meet their full demand.

To reduce the irrigation volume, irrigation techniques such as deficit irrigation (DI) have been developed meeting the minimum crop water requirement without any significant reduction in crop yield quality (Davies et al., 2002). In the last decades, one of the management options to overcome the agricultural drought is the use of partial root-zone drying (PRD) and regulated deficit irrigation (RDI) and they are called deficit irrigation methods whose application started on many crops in many countries in the world (Kang and Zhang, 2004). Partial root-zone drying is a deficit irrigation strategy designed to maintain in half of the root system in a dry or drying state, while the other half is irrigated, in order to keep the leaves hydrated. The treatment is then reversed, allowing the previously well-watered side of the root system to dry down while fully irrigating the previously dry side. RDI is a method where the entire root zone irrigated with the amount of water less than the maximum crop evapotranspiration. PRD technique developed at the knowledge of chemical signaling at the level of root-shoot in terms

of lack of water. In most cases, PRD irrigation has shown a great potential to increase irrigation water use efficiency (WUE) and to maintain yield (Davies and Hartung,2004). It has been shown that PRD can greatly induce the initiation and growth of secondary roots, which improve the ability of the plant to absorb both water (Liang et al., 1996) and nutrients from the soil matrix, which may increase the nutrient use efficiency (Han and Kang, 2002). Although several studies on N uptake by potato have been done (Mackand Schjoerring, 2002; Darwish et al., 2003, 2006), a thorough assessment of how different irrigation management strategies affect the N uptake in the plant-soil system under controlled environmental conditions is still lacking. The purpose of the present work was to study how PRD, RDI, and FI irrigation strategies affected nitrogen content in the soil-plant system during the growing season.

Materials and methods

Potato (*Solanum tuberosum* L.) cultivar Liseta was used for investigation. The experiment was carried out during the growing season of 2007 and 2008 in a vegetable commercial farm (Salate Centre) located 10 km north of Serbian capital, Belgrade. The irrigation method used was a drip subsurface method. The subsurface irrigation system was supplied by Netafim (A.C.S. Ltd. Netafim, Israel). For the FI and RDI treatments, one drip line was placed 0.1 m below the top of the ridge although in PRD treatment two drip lines were operated separately and were placed in parallel. The distance between emitters in FI and RDI treatments was 0.3 m and these were place exactly in the middle between two plants. PRD treatments the drip line consisted of two bundled lines each with 0.6 m distance. In partial root drying sealing one side takes until the amount of water in the second half is reduced by 20-30% of the total irrigation and the shifting time interval varied between 3 and 7 days depending on evaporative demand and soil water content. With the RDI and the PRD treatment is started after the phase of tuber initiation (when 80% of tubers more than 20 mm long). In the last 3 weeks of the irrigation period, 70% PRD and RDI was replaced by 50% (PRD and RDI plants received 50% of FI treatment). Because of longer irrigation period, during 2008 season, the number of harvest was increased to five (H1 –H5). Measurement of soil water content was done with a time domain reflectometer (TDR, TRASE, Soil Moisture Equipment Corp., USA). Plant nitrogen content in different plant organs (leaves, stems and tubers) was estimated by Kjeldahl method (Jones, 1990).

The measured traits have been analyzed for statistically significant differences by Students unpaired t - tests (Sigma Plot 6.0 for Windows - SPW 6.0, Jandel Scientific, Erckhart, Germany.

Results and discussion

Results of nitrogen content (Figures 1 and 2) in leaves, stem and tubers (Table 1) were carried out in order to determine whether PRD and RDI irrigation regimes can increase the efficiency of mineral nitrogen absorption from the soil and increase nitrogen translocation from leaves and the stem in the tuber. The positive effect of PRD and RDI irrigation regime on nitrogen absorption and transfer was at the end of the 2007 and 2008 vegetation period where there was a higher accumulation of nitrogen in the tubers. At the end of the experimental period, the PRD irrigation regimes increased nitrogen content in tubers by 11% in 2007. In 2008 at final harvest N content was by 16% ($P<0.05$) significantly higher in PRD than in FI plants. The maximum nitrogen values in both examined seasons, in the leaf and the stem were at the beginning of the vegetation, and then there was a decrease in value by the end of the examined period. These results in 2008 are also the result of the transition from static to dynamic irrigation. These results are in accordance with the Jovanović et al. (2008, 2010), which concluded that the PRD irrigation regime affects the increased translocation of N from the above-ground parts into the tubers and also increase the N – use efficiency. Our results show that the PRD irrigation regime has improved the accessibility of N from the soil, which

has influenced the development of the tuber at later stages of development and has positively affected the yield and size of the tuber. Similar results in potatoes were obtained by Shahnazari et al., (2008), where they also confirmed that PRD treatment may improve soil nitrogen availability during the late phases of potato growing season indicating a higher N mineralization and a greater accumulation of N in plant species. This all indicates that the PRD irrigation regime can improve the transport of nitrogen from leaf and stem to tuber at the end of the vegetation and increase the absorption of mineral nitrogen from the soil. Similar to our results, Shahnazari et al., (2008) found less residual nitrogen in soil at PRD compared to FI irrigation regime, which indicates higher accessibility of nitrogen from the soil to PRD plants, especially in later stages of development.

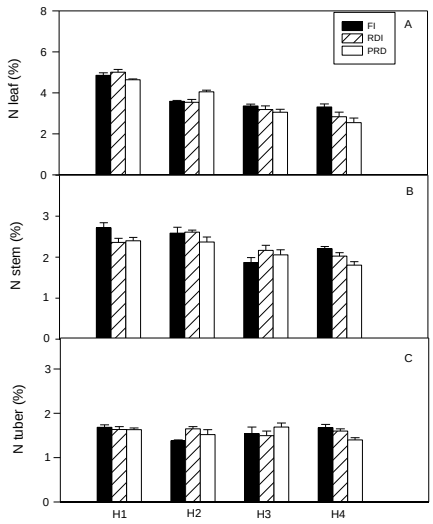

Fig.1.*Nitrogen content (in%) in the leaves (a), stems (b) and tuber (c) of potato plants under PRD,RDI and FI irrigation measured after different harvesting periods (H1,H2, H3 and final harvest) in 2007 experimental season. Bars are means ± S.E.*

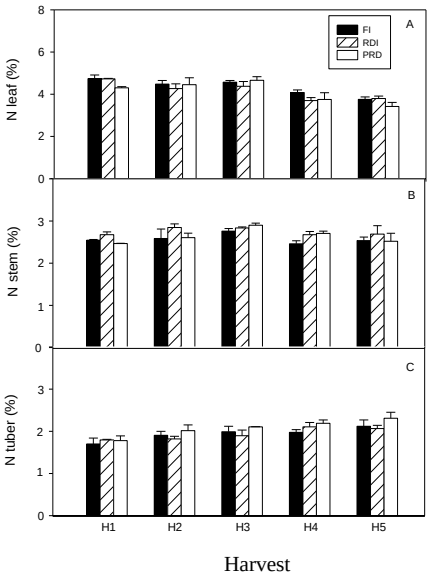

Fig.2.*Nitrogen content (in%) in the leaves (a), stems (b) and tuber (c) of potato plants under PRD,RDI and FI irrigation measured after different harvesting periods (H1,H2, H3,H4 and final harvest) in 2008 experimental season. Bars are means ± S.E.*

Table 1. Influence of FI, RDI and PRD regime of irrigation on content of N in tubers of potato in final harvest 2007 and 2008 years

	2007 year	2008year
Regime		
FI	2.18 ± 0.00	2.25 ± 0.15
RDI	2.30 ± 0.08	2.19 ±0.15
PRD	2.45 ± 0.08	2.68 ± 0.10

Conclusion

Experimental results for both seasons showed that PRD irrigated plants produced tubers with improved quality in terms of higher N content. Results showed, in both years, that N concentration in leaves and stems was progressively reduced during the growing season until final harvest when the lowest values were found in all irrigation treatments. In both years the

PRD treatments resulted in the increase in N in potato tubers. Results for N plant content indicated that PRD treatment could improve allocation of N from shoot to tuber at final harvest. N results might suggest a more beneficial effect of dynamic PRD approach than static PRD on plant growth.

Abstract

The production of bulk feed, with high protein contents, is one of the most important tasks of livestock production. Apart from pure legume crops, high yields of good quality bulk feed can also be achieved by grass-legume mixtures. In practice, temporary grasslands commonly known as grass-clover mixtures, usually comprise various types of grasses and legumes. Given that the quality of forage primarily depends on the botanical composition and stage of the development of plants at the time of grazing or cutting, the aim of this investigation was to determine the influence of the cutting regime on raw protein yield in different species of grasses and legumes in the plant community. A two-year study on protein yield showed that the cutting regime was a very important factor for obtaining high protein yields per unit of surface, since cutting at the flowering stage of legumes in all mixture variants resulted in a statistically significantly higher yield compared with those obtained at other cutting regimes. The maximum two-year protein yields at the cutting regime involving the flowering and budding phases of legumes were obtained by the S2 variant (3084 kg ha^{-1} and 2579 kg ha^{-1}, respectively), with high percentage of bird's-foot trefoil, while at the cutting regime involving the grazing imitation phase, the highest protein yield was obtained by the S3 mixture (2238 kg ha^{-1}) with equal representation of red clover and bird's-foot trefoil (20% each at sowing).

Key words: *temporary grassland, cutting regime, protein yield*

Introduction

In Bosnia and Herzegovina, livestock production is proclaimed as the most important part of agricultural especially in mountain regions into account the fact that food makes 60 to 70% of the total production cost, the production of good quality and cheap bulk feed is particularly important for the success of cattle production.

Perennial legumes, which represent the most important group of fodder plants, are characterized by high content of nutrients (proteins, minerals and vitamins). Perennial grasses are the basis of sustainable livestock farming as they make the basic food for ruminants in moderate climate areas, being components of both sown and natural pastures (Stošić, *et al.,* 2005; Lazarević, *et al.,* 1999), natural and sown meadows (Lazarević *et al.,* 2001) that can be used through cutting (Stošić and Radojević, 1980), silage and haylage (Dinić *et al.,* 2003). In addition to pure leguminous crops, high yields of high quality bulk feed can also be achieved by legume-grass mixtures since legumes contribute to soil fertility and improved nitrogen nutrition, thanks to their ability to fix highlight nitrogen from the soil, in symbiosis with *Rhizobia* bacteria. Therefore, proper choice and selection of types and species of grasses and legumes for grass-clover mixtures has a direct impact on the quantity and quality of the fodder as well as on the length of crop utilization. Namely, there are differences in the chemical composition between different types (Fairey, 2004) and varieties of grasses (Hussein *et al.,* 2002) and clover (Butler and Bailey, 1973), even at the same phytophenological stages of development. It should be particularly noted that the chemical composition of a lawn changes during the growing season, depending on the agro-ecological conditions, the applied agro-

technology, the manner and the intensity of exploitation. In addition to fertilization, the quality and yield of plant mass of sown grassland are largely dependent on the time (regime) of cutting, as well as on the way of cutting in terms whether or not it was mowed or grazed by different types of domestic animals (Marcela Andreata–Koren *et al.* (2009). Direct influence of the frequency of cutting on fodder quality was also pointed out by Minson (1990), who found that the content of crude proteins was higher by 90 g kg^{-1} SM and the content of fibers lower by 197 g kg^{-1} SM on the grassland that was mowed 4 times a year compared to the one mowed two times only.

The aim of the undertaken research was to determine the impact of cutting regimes on crude protein yields of different species of grasses and legumes in the plant community.

Material and Methods

A two-year research was conducted at the Butmir near of Sarajevo, experimental field (2012-2013). The experiment was set up using the random block method in four replications, with elementary plots of 5 m². The sowing was done manually, in rows with 12.5 cm spacing between the rows. The sowing rate was 15 kg ha^{-1} for red clover, 12 kg ha^{-1} for bird's-foot trefoil, 25 kg ha^{-1} for Italian ryegrass, 12 kg ha^{-1} for timothy grass and 30 kg ha^{-1} for orchard grass. Mineral fertilizer NPK (15:15:15) was used in pre-sowing preparation of soil in the amount of 250 kg ha^{-1}. Soil properties of the experimental field: pH-5.0 (in KCl), pH-5.7 (in H_2O); according to humus content of 2.6% it is medium humus soil; low to medium content of phosphorus amounting 9.8 mg/100 g of soil; according to the potassium content, the soil is medium provided with this element (20.8 mg/100 g of soil).

The experiment investigated:

(A) Two species of legumes and three species of grasses, in four replications of the composition of temporary grassland, as follows:

1. Red clover (*Trifolium pratense* L.) 40%, Italian ryegrass (*Lolium italicum* L.) 20%, timothy grass (*Phleum pratense* L.) 20%, orchard grass (*Dactylis glomerata* L.) 20% (Mixture S1).
2. Bird's foot trefoil (*Lotus corniculatus* L.) 40%, Italian ryegrass (*Lolium italicum* L.) 20%, timothy grass (*Phleum pratense* L.) 20%, orchard grass (*Dactylis glomerata* L.) 20% (Mixture S2). 3. Red clover (*Trifolium pratense* L.) 20%, bird's foot trefoil (*Lotus corniculatus* L.) 20%, Italian ryegrass (*Lolium italicum* L.) 20%, timothy grass (*Phleum pratense* L.) 20%, orchard grass (*Dactylis glomerata* L.) 20% (Mixture S3). 4. Italian ryegrass (*Lolium italicum* L.) 33.3%, timothy grass (*Phleum pratense* L.) 33.3% orchard grass (*Dactylis glomerata* L.) 33.3% (Mixture S4).

(B) Three cutting variants a) Cutting at a height of 20 cm (grazing imitation), b) Cutting in the budding phase of the leguminous component, c) Cutting in the flowering phase of the leguminous component. The content of total nitrogen in the plant mass was determined by the Kjeldahl method. Crude protein content was determined based on the level of total nitrogen in dry matter multiplied by factor 6.25. Crude protein yield (CP) was determined on the basis of dry mass yield and the content of crude proteins in it. The test results were processed using mathematical and statistical methods in SPSS and Excel programs.

Results and Discussion

Comparative value of protein yields at different cutting regimes in 2012

In addition to the botanical composition of the mixtures, the cutting regime also had a significant effect on the yield of crude protein (Table 1.), as statistically significantly higher yield of proteins was obtained at cutting in the flowering phase of legumes compared to protein yields obtained at the previous two cutting regimes. There was also a significant difference in the yield of proteins obtained at cutting in the budding phase of legumes compared to the yield obtained in the phase of grazing imitation (except in mixture S4).

The highest protein yield at cutting in the flowering phase of legumes was achieved by mixture S1 (1764 kg ha^{-1}), while the highest yield of crude protein in the phase of grazing imitation and budding of legumes was achieved by mixture S3 (1115 kg ha^{-1} and 1342 kg ha^{-1}).

Table 1. Comparative value of proteins (kg ha^{-1}) in 2012 at different cutting regimes

Mixture variant (Temporary grasslands)	**Cutting regime**		
	Grazing imitation	**Budding**	**Flowering**
Mixture (S1)	1022c	1220b	1764a
Mixture (S2)	652c	1131b	1393a
Mixture (S3)	1115c	1342b	1573a
Mixture (S4)	363b	340b	403a
Average	**788**	**1008**	**1283**

[abc] Values marked with different letters are showing significant differences among cutting regime (P<0.05)

The lowest yield of crude protein, in all phases of development at the time of cutting was found in mixture S4, and its values amounted to 340 kg ha^{-1} (the budding phase of legumes), 363 kg ha^{-1} (the phase of grazing imitation) and 403 kg ha^{-1} (the flowering phase of legumes).

Comparative value of protein yields at different cutting regimes in 2013

The highest average protein yield (1281 kg ha^{-1}) in 2013 was achieved by cutting at the flowering phase of legumes (Table 2.), followed by the budding phase of legumes (1112 kg ha^{-1}), and the lowest at the phase of grazing imitation (1076 kg ha^{-1}). The statistically significantly higher protein yield, regardless of the type of mixture, was obtained by cutting at the flowering phase of legumes (with the exception of mixture S4) compared to the yield obtained by cutting at the budding phase of legumes or the grazing imitation phase. The S2 mixture achieved the maximum yield of crude protein in all cutting variants, ranging from 1435 kg ha^{-1} (grazing imitation phase) to 1690 kg ha^{-1} (legumes flowering phase). The S4 variant, consisting only of grasses, had the lowest crude protein yield at all cutting regimes.

Table 2. Comparative value of proteins (kg ha-1) in 2013 at different cutting regimes

Mixture variant (Temporary grasslands)	**Cutting regime**		
	Grazing imitation	**Budding**	**Flowering**
Mixture (S1)	1017b	1082b	1279a
Mixture (S2)	1435b	1447b	1690a
Mixture (S3)	1122b	1156b	1418a
Mixture (S4)	729a	762a	738a
Average	**1076**	**1112**	**1281**

[ab] Values marked with different letters are showing significant differences among cutting regime (P<0.05)

The minimum protein yield for this mixture was recorded in the cutting at the phase of grazing imitation, only 729 kg ha^{-1}, followed by slightly higher yield of cutting at the flowering phase (738 kg ha^{-1}), and at the budding phase of legumes 762 kg ha^{-1}.

Weather conditions that were slightly more favorable during the vegetation period compared to the year 2012, contributed to the results of this year's research, because although the annual

sum of precipitation was lower relative to the multi-year average, there were no extreme droughts, while temperatures were mostly slightly higher compared to those in the multi-year average.

Comparative two-year protein yield at different cutting regimes

The two-year study on protein yields has shown that the cutting regime had a significant effect on the yield of proteins achieved per unit of surface, (Table 3.) since cutting in the flowering phase of legumes, in all mixture variants, resulted in a statistically significantly higher yield compared to the yields obtained by other cutting regimes.

However, if we compare the protein yield obtained in the other two cutting regimes, it can be concluded that cutting in the budding phase of legumes can obtain a significantly higher protein yield compared to the one obtained at cutting in the phase of grazing imitation.

On the other hand, the influence of the botanical composition, i.e. composition of the mixtures, on protein yields was clearly pronounced. In our research, the highest two-year protein yield at the cutting regime in the flowering phase of legumes, as well as in the budding phase of legumes, was obtained by variant S2 (3084 kg ha^{-1} and 2579 kg ha^{-1}), with a high percentage being bird's foot trefoil, while at the cutting regime in the phase of grazing imitation it was the mixture S3 (2238 kg ha^{-1}) in which red clover and bird's foot trefoil were equally represented (20% each at sowing).

Table 3. Comparative value of the two-year protein yield (kg ha^{-1}) at different cutting regimes

Mixture variant (Temporary grasslands)	**Cutting regime**		
	Grazing imitation	**Budding**	**Flowering**
Mixture (S1)	2040c	2302b	3043a
Mixture (S2)	2087c	2579b	3084a
Mixture (S3)	2238c	2499b	2991a
Mixture (S4)	1092c	1102b	1141a
Average	**1864**	**2120**	**2565**

[abc] Values marked with different letters are showing significant differences among cutting regime ($P<0.05$)

The yield of crude proteins in red clover, bird's foot trefoil, timothy grass, Italian ryegrass, orchard grass and their mixtures indicates that mixtures with a higher content of red clover and bird's foot trefoil produce or can produce higher yields of crude proteins per unit of surface. This is particularly evident in mixtures with a higher proportion of bird's foot trefoil (phase of budding and flowering of legumes), and red clover in the phase of flowering of legumes, where their participation in the mixture was 40%, which quite corresponds to the results of Hannaway *et al.* (1999), Jose *et al.* (2001), Bezdrob *et al.* (2013).

Conclusions

Based on the results obtained in this research, the following can be concluded:

Two-year results of the study on crude protein yields have shown that the cutting regime had a statistically significant effect on the protein yield achieved, where significantly positive differences were obtained at each subsequent cutting regime, irrespective of the botanical composition of the mixtures.

The S2 mixture, consisting of bird's foot trefoil, Italian ryegrass, timothy grass and orchard grass, achieved the highest two-year protein yield in the legumes flowering phase (3084 kg ha^{-1}) and the budding phase (2579 kg ha^{-1}), while the mixture S3 had the highest protein yield in the phase of grazing imitation (2238 kg ha^{-1}).

The mixture of grasses had the lowest total protein yield at any cutting regime - it was even two times lower compared to the average value of all studied mixtures. This shows that leguminous plants ((in our case red clover and bird's foot trefoil), regardless of their participation in the mixtures, had a positive effect on protein yield as their yield was significantly higher compared to the protein yield in grass mixtures.

Abstract

The Balkan Peninsula is considered a secondary centre of genetic diversity of wild pear. To this point, the population of wild pears in Bosnia and Herzegovina (B&H) has not been the subject of comprehensive research. Certain areas are characterized by a large variety of wild pears, one of which is Kozara mountain. The aim of these researches is the morphological characterization of *in situ* populations of wild pear on Kozara mountain, Previja locality (B&H) and the separation of the accessions with certain positive characteristics for selection of varieties and rootstocks. In Bosnia and Herzegovina and in many European countries the wild pear is the main seedling rootstock for grafting cultivated pears. There are nine (9) accessions inventoried in the locality of Previja. The morphological characterization of the vegetative organs of the selected pear trees was performed during two-year period (2012 and 2014) and the following parameters were analyzed: tree trunk characteristics (vigour and habit), characteristics of one-year-old shoots (bark colour, lenticels appearance, length of internodes) and leaf characteristics (leaf blade length and width, petiole length and the appearance of the stipule on the petioles, the shape of the apex and the base of the leaf blade, the shape of the leaf blade). The pomological characterization of the fruits of the selected accessions was carried out during 2012 and 2016 years with the following characteristics: fruit weight, height and width and fruit shape index, number of seeds in fruit, length and thickness of the stalk. The fruit trees had weak to medium vigour with the upright position of branches in most of the analyzed trees. The average weight of fruit of all the accessions in 2012 (15.12 g) was lower than in 2016 (21.01 g). The KP3 accession is distinguished by the number of seeds in the fruit, which is characterized by more than 2 seed germs in one seed case.

Keywords: *Wild pear, Morphological characterization, Leaf, Fruit.*

Introduction

Wild pear (*Pyrus communis* L.) is a valuable and significant forest fruit tree because of its nutritional value (production of distillates, honey), utilisation in fruit production (used as a rootstock for grafting) and wood value. It is a companion of deciduous forests in the Balkan Peninsula and has a wide distribution range (Mratinić and Kojić, 1998). It is also found in both the plains and mountainous areas up to 1,600 m above sea level. Balkan Peninsula is considered a secondary centre of genetic diversity of wild pear. Wild pear is a significant source for genetic improvement and creation of new varieties and rootstocks, but so far it has rarely been used in breeding programs. Most wild fruit tree *in situ* conditions have not been sufficiently explored and processed, as is the case with populations of wild pears in Bosnia and Herzegovina.

Significant studies of wild pear populations in the areas of former Yugoslavia were carried out in the area of Bijelo Polje (Jovančević, 1994), Sarajevo (Kulina, 2001), Western Serbia (Milutinović et al., 2005) and indigenous pear populations in XX area (Paunović et al., 2012). Biodiversity of wild fruit trees in Europe is endangered by the increasing intensification of agriculture and urbanization as well as genetic crossing with cultivated species (Stephan et al.,

2003). Therefore, in areas where it is expected that the existing population of wild fruit trees contains useful properties, it is necessary to carry out the collection of the material and its conservation. Parallel to conservation, description, characterization and evaluation should be performed. The study of phenotypic traits of natural populations is not only relevant for the observation of biological heritage, but also as a potential source of genes for improving cultivated plants (Marino et al., 2013). Mountain areas up to 1.000 m altitude are characterized by the rich and still well-preserved wild pear populations, and one of them is the Kozara mountain, located in the north-western part of Bosnia and Herzegovina. The aim of these researches is the morphological characterization of *in situ* populations of wild pear on the Kozara mountain, the Previja area (B&H) and the collection of accessions with certain positive characteristics for varieties and rootstock selection programs.

Material and Methods

The morphological characterization of wild pear (*Pyrus communis* var. *pyraster* (L.) Ehrh.) included nine (9) *in situ* populations in the Previja area, located on the southeast slopes of the Kozara mountain. Inventory of wild pear trees was carried out on the basis of the vigour, the type of growth and the characteristic of the fruit (size, shape and number of seeds). The accessions are mapped by a hand GPS receiver (GARMIN Oregon 550, USA) and are marked with PCK (PC-*Pyrus communis*, K-Kozara) and numbered from 1 to 9.

The morphological characterization of the vegetative organs of the trees of chosen accessions was carried out during the period 2012 and 2014 years in accordance with the International UPOV (The International Union for the Protection of New Varietes of Plants) descriptors for pear (UPOV, 2000). The trees are characterized by the properties of the vigour and the position of the branches (habit). On the sample of 10 annual shoots we analyzed the following properties: the bark colour on the sunny side, the appearance of lenticels and the length of the internodes. The analysis of the leaf characteristics was conducted on a sample of 25 leaves taken from the central part of the young shoots and the following characteristics were noted: length and width of the leaf blade, the length of the petiole and the occurrence of the stipules on the leaf petiole, the shape of the tip and the base of the leaf blade and the shape of the leaf blade. The analysis of the young shoots and leaves was performed at the end of June, at the end of intensive growth. The pomological characterization of collected fruits was carried out during the season of fruit ripening during 2012 and 2016 years on an average sample of 25 fruits, with the following characteristics: fruit weight, height, width and index of fruit shape, number of seeds in fruit, length and thickness of peduncle.

The data were statistically analyzed by a variance analysis method for a two-factor trial. The significance of the differences was determined by the LSD test for the significance level of $p<0.05$. The absolute variability of the mean values is defined by calculating the standard error (SE). For all studied characteristics, apart from the fruit weight, the coefficients of variation (CV) were calculated.

Results and Discussion

An overview of the characteristics of trees and young shoots of inventoried wild pears is shown in Table 1. In the Balkan researches (Paunović et al., 2012), a vigorous to very vigorous wild pear trees were recorded. In the population of wild pear at the Kozara site, trees with low and medium vigour and upright growth type (habitat) were dominant. Lenticels on one- year- old wild pear shoots from the Kozara site are present in a smaller number, and the bark colour of the accessions are generally various shades of brown, except for the two accessions in which they were gray-green (PCK6 I PCK9).

Table 1. Characteristics of trees and young shoots of wild pear trees *in situ*

Accessions	Tree		One-year-old shoot		
	Vigour	Habit	Colour	Number of lenticels	Length of internodes (cm)
PCK1	weak	spreading	brown red	many	1.96
PCK2	weak	upright	medium brown	few	1.91
PCK3	medium	upright	medium brown	medium	2.14
PCK4	weak	upright	brown red	medium	2.34
PCK5	medium	upright	orange brown	medium	2.16
PCK6	medium	upright	grey green	many	2.30
PCK7	medium	spreading	brown red	medium	1.81
PCK8	medium	semi-upright	brown red	medium	2.19
PCK9	strong	upright	grey green	few	2.37

The qualitative characteristics of the leaves of the selected of wild pear trees are shown in Table 2.

Table 2. Leaf characteristics of *in situ* wild pear accessions

Accessions	Leaf blade			
	Shape of base	Shape of apex	Incisions of margin	Presence of stipules
PCK1	truncate	obtuse	bluntly serrate	absent
PCK2	cordate	obtuse	crenate	absent
PCK3	truncate	obtuse	crenate	absent
PCK4	cordate	right-angled	absent	present
PCK5	truncate	right-angled	bluntly serrate	present
PCK6	obtuse	obtuse	absent	absent
PCK7	truncate	obtuse	crenate	absent
PCK8	truncate	obtuse	crenate	present
PCK9	truncate	acute	bluntly serrate	absent

Most of the selected accessions, i.e. 65% of them, had truncated leaf base form, the obtuse shape of the leaf tip, and the leaf without stipules.

Data on the quantitative characteristics of wild pear leaves are shown in Table 3. Measurements of the leaf characteristics were carried out during two different years regarding the climatic conditions. The 2012 was extremely dry, and 2014 was with a lot of precipitation. The values of leaf dimensions are uniform, with a small variation coefficient of measured properties. A higher variation in the width of the leaf (CV> 15%), with a certain number of accessions, was more pronounced during the dry year (2012). The length of the leaf petiole was between 1.01 cm and 3.76 cm. Accession PCK9 had the longest leaf petiole in average. The leaf dimensions are uniform, and the values of the petiole length are highly variable, and are confirmed by the coefficient of variation (CV), which is, by the length of the petiole, higher than the CV of leaf dimensions characteristics.

Table 3. A quantitative characteristic of leaves of wild pear accessions

Accessions	Year	Leaf blade					
		Length (cm)	CV (%)	Width (cm)	CV (%)	Length of petiole (cm)	CV (%)
PCK1	2012	3.45±0.31	9.03	2.88±0.16	5.56	2.43±0.43	17.75
	2014	3.79±0.29	7.64	3.35±0.27	7.94	1.01±0.20	19.71

	2014	5.18±0.49	9.51	3.66±0.32	8.85	1.76±0.24	13.63
PCK6	2012	5.41±0.56	10.39	4.20±0.75	17.75	2.88±0.45	15.64
	2014	6.20±0.57	9.26	4.34±0.38	8.82	2.72±0.40	14.60
PCK7	2012	5.13±0.64	12.39	4.70±0.56	11.96	3.06±0.85	27.87
	2014	4.59±0.52	11.42	3.24±0.46	14.31	1.64±0.50	30.56
PCK8	2012	5.52±0.49	8.93	4.72±0.47	10.04	3.08±0.42	13.51
	2014	5.33±0.44	8.32	4.28±0.64	14.93	2.14±0.45	21.14
PCK9	2012	5.41±0.61	11.31	3.94±0.32	8.18	3.36±0.87	25.97
	2014	6.26±0.42	6.72	4.36±0.54	12.29	3.76±1.44	38.27

The analysis of fruit characteristics of wild pear accessions was carried out over two years, with different climatic factors, in 2012 (dry year) and in 2016 (a year with a favourable precipitation distribution during the growing season). The average values of the weight of the fruit of all tested accessions were higher in 2016 (Table 4), except for PCK7. Four wild pear accessions (PCK1, PCK2, PCK5 and PCK7) had relatively small fruits, weighing up to 10 g. By the size of the fruit, the accession PCK9 is identified with a fruit weight of 42.54 g.

Table 4. Average fruit mass (g) of wild pear accessions

Accessions	Year		Average
	2012	2016	
PCK1	7.40	12.16	9.78
PCK2	6.83	9.89	8.36
PCK3	8.70	19.21	13.95
PCK4	18.10	37.52	27.81
PCK5	7.45	10.68	9.06
PCK6	17.35	19.27	18.31
PCK7	10.32	8.39	9.35
PCK8	19.33	26.84	23.08
PCK9	40.60	44.49	42.54
Average	15.12	20.93	
Level	A	B	AB
F calculated	383.99**	221.68**	27.67**
$LSD_{0.05}$	1.66	0.78	2.35
$LSD_{0.01}$	2.22	1.05	3.15

**statistically highly significant difference; A-accession factor; B-year factor; AB-interaction accessions/year

There are statistically significant differences in the weight of the fruit between analyzed accessions, years of research and the interaction of the accession/year. The results of our research are similar to those of Jovančević (1994) and Paunović et al. (2012). The average mass of wild pear populations of the Bijelo Polje area was 15.84 g (Jovančević, 1994), and in the researches of indigenous populations in Serbia it was 20.05 g, and the highest fruit mass had the genotype K1 (31.17 g) (Paunović et al., 2012). In our research, the accession PCK9 had an average maximum weight of fruit 42.54 grams. The fruits of autochthonous pear varieties "Karamut", "Zobnjača", "Žutica" in the territory of Bosnia and Herzegovina (Đurić et al., 2015) have a lower mass of fruit than the accession PCK9.

The results of measuring the wild pear fruits are shown in Table 4. Wild pear fruit, other than crown, is characterized by a shape that determines the ratio of height and width of the fruit. According to Mišić (1984), wild pear fruits are small, spherical or pear shaped, hard and bitter. The fruits from the Kozara locality are mainly roundly shaped, with the exception of the PCK3 which have a pear shape of the fruit (fruit shape index> 1). The number of normally developed seeds of wild pear fruit varies from 1.2 to 10.1 (Mratinić, 2001). In research in the area of Trebević (Kulina, 2001) the fruit of wild pear had an average of 5.36 seeds and in research of Paunović et al., in Serbia (2012) it contained 3.89 developed seeds. The analysis of wild pear population at the Kozara site showed an average of 5.35 seeds in fruit. By the number of seeds, the accession PCK3 is set apart, and the fruit is distinguished by more than two seeds of embryos in a single seed box, resulting in fruit with more than 10 seeds per fruit. The number of fruit seeds is characterized by high variability. In addition to the PCK3, the accessions PCK4, PCK1 and PCK8 can be separated by a relatively high number of seeds. The aforementioned accessions should be the subject of selection of rootstocks mother trees with further testing of seed germination and seedling characteristics.

Table 5. Fruit quantitative traits of in situ wild pear accessions

Accessions	Year	Fruit					
		Fruit shape index	CV (%)	Peduncle length (cm)	CV (%)	Number of seeds in fruit	CV (%)
PCK1	2012	0.92±0.08	8.37	2.34±0.30	13.02	5.81±2.10	36.21
	2016	0.87±0.05	5.86	1.84±0.20	11.04	5.88±1.36	23.15
PCK2	2012	0.90±0.06	6.55	2.16±0.33	15.24	3.94±1.57	39.85
	2016	0.88±0.03	3.39	3.70±0.28	7.58	5.63±2.39	42.51
PCK3	2012	1.17±0.06	5.35	3.62±0.41	11.25	8.94±1.24	13.84
	2016	1.25±0.08	6.19	2.50±0.32	12.79	9.19±1.91	20.74
PCK4	2012	0.89±0.05	5.56	1.55±0.48	30.95	7.63±1.02	13.44
	2016	0.86±0.07	7.74	1.72±0.26	14.97	6.81±1.94	28.47
PCK5	2012	0.85±0.04	5.11	3.00±0.29	9.77	3.69±1.45	39.26
	2016	0.80±0.03	3.49	3.02±0.32	10.65	4.13±1.78	43.25
PCK6	2012	0.88±0.04	4.54	3.09±0.39	12.46	2.31±2.24	96.98
	2016	0.92±0.08	9.20	3.23±0.32	9.99	1.81±0.98	54.13
PCK7	2012	0.88±0.04	4.18	2.14±0.31	14.39	3.88±2.16	55.65
	2016	0.85±0.03	3.51	2.83±0.25	8.76	6.56±1.59	24.23
PCK8	2012	0.90±0.06	6.23	2.75±0.35	12.64	4.69±1.96	41.75
	2016	0.87±0.05	5.68	2.89±0.42	14.54	6.75±2.72	40.30
PCK9	2012	0.87±0.03	3.25	3.37±0.22	6.64	3.56±1.46	40.96
	2016	0.85±0.03	3.40	3.61±0.41	11.36	4.69±1.89	40.27

The values of fruit peduncle length were between 1.55 cm and 3.70 cm. Four accessions had relatively long fruit peduncle longer than 3 cm in average. The PCK9 had the longest peduncle. Most of the fruit peduncles were longer in 2016.

Conclusions

The Balkan Peninsula is considered a secondary centre of genetic diversity of wild pear, and Kozara locality is one of the more important areas of wild pear genetic diversity. The wild relatives of cultivated varieties represent an important part of plant genetic recourses of a country. The research of wild pear population in Kozara locality shows the great population diversity which can be highly significant in breeding programs of pear varieties and rootstocks. As a significant starting material for breeding work, several accessions can be set apart. Based on the number of seeds in the fruit in the pre-selection of seedling rootstocks for pears accessions PCK3, PCK1, PCK4 and PCK8 can be used. For the breeding of new varieties of pears on the basis of the fruit characteristics (mass and shape) the PCK9, PCK4, PCK8 and PCK3 are suitable.

Abstract

Pomegranate (*Punica granatum* L.) has long been domesticated in our area and it is rightfully considered as one of the autochthonous species of Herzegovinian karst. In lower karst areas, pomegranate occurs in various types of habitats and grows individually or in larger and smaller groups, forming pure populations or populations mixed with other species such as spruce, Jerusalem thorn and others. Wild pomegranate, known under the names *ljutun* and *ljutunac* (*P. granatum* var. *spontanea*) is different from cultivated pomegranate or *sladun*, *sladunac* (*P. granatum* var. *sativa*). A study of the wild-grown population of pomegranate was conducted at several sites in Herzegovina during two vegetation years, 2013 and 2014. In this study, the following pomegranate fruit properties were measured in 11 accessions (phenotypes) from the natural population: fruit weight (g), arils weight (g), weight of 100 arils (g), peel weight (g), peel thickness (mm), fruit height (mm), fruit width (mm), fruit crown height (mm), and fruit crown width (mm). Portions of peel and arils (%) were also determined. The average fruit weight ranged from 73.56 g to 114.82 g. The weight of most samples was higher in 2014 than in 2013. The average arils weight ranged from 32.87 g to 56.76 g. The average portion of arils in 2013 was 41.68% and 50.15% in 2014. The obtained data indicate significant effects of environmental conditions in individual years on properties of the same accessions at some locations, but also significant interaction effects between locations, years and accessions. The year factor had a greater influence on physical parameters of the wild pomegranate fruits than the location factor.

Keywords: *Wild pomegranate (Punica granatum L.), Location, Environmental conditions, Pomometric properties.*

Introduction

Pomegranate (*Punica granatum* L.) has long been domesticated in our area and it is rightfully considered as one of the autochthonous species of Herzegovinian karst, where along with fig and olive represents one of the oldest cultivated fruit species of the Mediterranean and Middle East regions. According to literature data, pomegranate is native to a region of Iran, Afghanistan, the Urals, the southern part of the Caspian Sea and from these areas it spread to the areas around the Mediterranean Sea (Kušan, 1938). Pomegranate was most probably brought to our region and surrounding areas by the Greeks and Romans. Pomegranate is widely distributed along the Adriatic Sea and in river valleys dominated by the Mediterranean influence, the rivers of Neretva in Herzegovina, Krka in Dalmatia and Zeta in Montenegro (Redžić, 1952). In Bosnia and Herzegovina, wild pomegranate is found around Mostar, Blagaj, Stolac, Ljubuški, Čitluk, Grude, Čapljina, part of the Široki Brijeg municipality, Neum and Trebinje. Pomegranate grows from the sea coast up to 580 meters above sea level. The most favorable conditions for growth and development are at altitudes from 20 to 150 meters above sea level, where populations of wild pomegranate are also the most numerous (Ćemalović, 1979).

The fruits of wild pomegranate are smaller than the fruits of cultivated pomegranate. It is a heliophytic plant species that grows alone or in sparse densities in insolated places.

Populations of wild pomegranate predominantly occur on skeleton texture soils of neutral to alkaline pH reaction (Ćemalović, 1979). Pomegranate fruit, root, tree bark, seeds and flower can be used for various purposes. Pomegranate tree bark is rich in tannins and pectins, so it is used for production of pectin, and in leather industry for tanning leather (Džubur, 2007). The beneficial effect on human health is attributed to the content of polyphenolic compounds, particularly anthocyanins, which are characterized by high antioxidant activity and are involved in the neutralization of free radicals responsible for many acute and chronic diseases (Lansky and Newman, 2007, Adhami and Mukhtar, 2006, Reddy *et al*., 2007). Wild pomegranate fruit is not used as table fruit, but only for processing into juices. In the process, it can be blended with cultivated pomegranate juice and grape juice. Pomegranate juice is consumed fresh, in sorbets, it is used for making jellies, cold or warm sauces. Wild pomegranate is morphologically different from cultivated pomegranate varieties (Ćemalović, 1979). The aim of this study was evaluation of the studied wild pomegranate accessions in selected locations of Herzegovina based on pomometric description criteria.

Material and Methods

A study of the wild-grown population of pomegranate was conducted during two vegetation years, 2013 and 2014, in several locations in Herzegovina: Mostar, Počitelj, Međugorje, Stolac and Čapljina. Selection of bushes was carried out on the basis of morphological characteristics of bushes and fruits. A total of 11 wild pomegranate accessions (phenotypes) from the natural population were selected, marked with letters and numbers in the following order: RK1 and RK2 (Mostar), PO1 and PO2 (Počitelj), MK and MNJ (Međugorje), PB1, PB2, PNJ1 and PNJ2 (Stolac) and TR (Čapljina).

Harvesting of wild pomegranate fruit was carried out at the stage of full ripeness in the first half of November. Ten approximately equal wild pomegranate fruits were taken from each of the selected bushes. They were brought to the laboratory, where pomometric measurements of the fruits were conducted. The following wild pomegranate fruit properties were measured in this study: fruit weight (g), arils weight (g), weight of 100 arils (g), peel weight (g), peel thickness (mm), fruit height (mm), fruit width (mm), fruit crown height (mm), fruit crown width (mm). Fruit weight, arils weight and peel weight were measured on technical scale (Kern 440-45). Fruit height, width, crown height and width, peel thickness were measured by digital slide rule (Hm Müllner werkzeuge). Fruit height was measured from fruit top (crown) to fruit peduncle and fruit width was measured transversely to the previous measurement. Portion of peel (%) was calculated from the ratio of peel weight to fruit weight and portion of arils (%) from the ratio of arils weight to fruit weight.

Research data were statistically processed by variance analysis (ANOVA), and then the differences between mean values of the eleven analyzed accessions were examined by LSD test for all significant F tests with the level of significance $p \leq 0.01$. Variance analysis was performed for both study years, and after variance homogeneity tests, a common variance analysis was conducted for both years and for all analyzed properties. The statistical program SP SS 16 (*Statistical Package for the Social Sciences*) and MS Excel 2007 were used for data processing.

Results and Discussion

In both study years, the biggest average fruit height was found in accession PB1 (location Stolac) of 52.26 mm and smallest in accession PO2 (location Počitelj) of 44.42 mm (Table 1). Wani *et al*. (2012) reported the values of fruit height of wild pomegranate genotypes from 59.0 mm to 92.4 mm, while Muradoğlu *et al*. (2006) found average wild pomegranate fruit heights from 60.0 mm to 81.0 mm. A partial agreement can be established by comparing literature data with results of the conducted research and the differences are probably due to

different environmental conditions. Cultivated varieties are characterized by larger fruits, so it stands to reason that they have a greater fruit height. Thus, Gadže (2013) presented average fruit heights of the studied cultivated varieties from 67.18 mm to 85.83 mm.

The biggest average fruit width of 60.05 mm was determined in accession PNJ2 (location Stolac) in both years, while the smallest average fruit width of 50.46 mm was found in accession PO2 (location Počitelj) (Table 1), which coincides with the results of Muradoğlu *et al*. (2006) who reported the average wild pomegranate fruit width values from 30.8 mm to 88.9 mm and Wani *et al*. (2012) from 65.4 mm to 98.4 mm. Different fruit width data were found for cultivated varieties. Thus, Mars and Marrackhi (1999) described average pomegranate fruit widths from 57.6 mm to 111.4 m and Gadže (2013) from 75 mm to 101.12 mm.

The biggest average fruit crown height for both years was found in accession TR (location Čapljina) and it amounted to 14.18 mm, and the smallest average height of 11.91 mm was measured in accession RK2 (location Mostar) (Table 1). Muradoğlu *et al*. (2006) presented crown height values ranging from 11.0 to 26.1 mm, Tehranifar *et al*. (2010) reported the values in the range from 13.45 mm to 24 mm. In cultivated pomegranate varieties, Gadže (2013) presented the values from 17.46 mm to 22.07 mm. It can be concluded that the crown height values of studied wild pomegranate accessions were closer to the lower values of the above-mentioned authors.

The biggest average value of fruit crown width of 16.69 mm was measured in accession PO1 (location Počitelj), and the smallest of 12.73 mm in accession RK2 (location Mostar) (Table 1). Muradoğlu *et al*. (2006) reported the crown width values in wild pomegranate from 11.2 mm to 18.1 mm, which coincides with the results of these studies.

The biggest average peel thickness of 3.44 mm was found in accession TR (location Čapljina), and the smallest of 2.39 mm in accession RK2 (location Mostar) (Table 1). For average wild pomegranate peel thickness, Ćemalović (1979) registered the values from 2 to 4 mm, which means that the peel thickness from this research had similar values to the above-mentioned values. Wani *et al*. (2012) reported the peel thickness in wild pomegranate genotypes between 1.81 mm and 3.64 mm, and Muradoğlu *et al*. (2006) from 1.7 mm to 4.0 mm.

Fruit weight is genetically determined, but also influenced by the climatic factors, as well as substrate (soil) on which the wild pomegranate bush grows. The biggest average fruit weight was found in accession PNJ2 (location Stolac) and it was 114.82 g and the smallest value of 73.56 g was measured in accession PO2 (location Počitelj) (Table 1). In his research, Ćemalović (1979) described the wild pomegranate fruit weight as ranging from 30 to 230 g, which is in agreement with the results of this research. Tabur *et al*. (1987) reported the fruit weight values from 175 g to 259 g, and Muradoğlu *et al*. (2006) reported the wild pomegranate fruit weight values in the range from 131.6 g to 337.1 g, which are higher values in relation to the results of this research.

The biggest average arils weight of 56.76 g was found in accession PB1 (location Stolac), and the fruit of accession PO2 (location Počitelj) had the smallest average arils weight of 32.87 g (Table 1).

Table 1. Average values of pomometric properties of wild pomegranate fruit in two years (2013/14)

* Different letters within columns indicate significant differences between the samples based on LSD test (P= 5%; P= 1%)

Ercan *et al*. (1992) reported the arils weight values of studied pomegranate genotypes in the range from 34.0 g to 63.6 g, and Zarei *et al*. (2011) the value of 136.13 g. Gadže (2013) reported that the average arils weight in cultivated pomegranate varieties ranged from 145.01 g to 274.44 g.

The biggest average weight of 100 arils in both years of 19.18 g was in accession RK1 (location Mostar), and the smallest weight of 100 arils of 11.55 g was in accession PO2 (location Počitelj) (Table 1). It is apparent that both the smallest and the biggest average values of weight of 100 arils in these studies were lower in relation to the research of Muradoğlu *et al*. (2006) who described the values for weight of 100 arils of wild pomegranate in the range from 18.5 to 35.0 g. Drogoudi *et al*. (2005) pointed out that aril size is one of the most important factors affecting the quantity of juice and generally pomegranate edibility and reported values of weight of 100 arils from 17.5 g to 66.7 g.

The biggest average peel weight of 60.71 g was measured in accession PNJ2 (location Stolac), and the smallest of 39.26 g in accession PO2 (location Počitelj) (Table 1). Wani *et al*. (2012) reported the values of peel weight in wild pomegranate genotypes from 60 g to 217.75 g, Al-Maiman and Ahmad (2002) reported the value of 69.01 g for peel weight.

The portion of arils in fruits of the studied wild pomegranate accessions ranged from 34.62% to 56.45% with average values of 41.68% in 2013 and 50.15% in 2014 (Table 2).This is consistent with the results of Ercan *et al*. (1992) who presented the values from 43.2% to 62.5%, and Muradoğlu *et al*. (2006) with values from 49.5% to 71.5%.

Table 2. Portions of arils and peel in wild pomegranate fruit

Sample	2013		2014	
	Arils portion (%)	Peel portion (%)	Arils portion (%)	Peel portion (%)
RK1	48.86	51.14	52.27	47.73
RK2	54.53	45.47	56.45	43.55
PO1	34.62	65.38	46.39	53.61
PO2	39.40	60.60	48.59	51.41
MK	45.99	54.01	49.29	50.71
MNJ	43.87	56.14	53.50	46.51
TR	44.36	55.64	50.38	49.62
PB1	45.38	54.62	52.42	47.58
PB2	46.66	53.34	47.80	52.21
PNJ1	46.86	53.14	45.37	54.63
PNJ2	46.84	53.16	49.22	50.78
Average value	**41.68**	**54.79**	**50.15**	**49.85**

The portion of peel in wild pomegranate fruit ranged from 43.55% to 65.38%, and the average values were 54.79% in 2013 and 49.85% in 2014 (Table 2). The results generally correspond to the wild pomegranate peel portion data reported by Wani *et al*. (2012) from 32.6% to 56.05%, while Tabur *et al*. (1987) indicated slightly smaller portion of peel from 28.0% to 39.2%. The ratio of peel and arils or arils yield is a very important property of fruit, and especially in fruits for industrial processing. In this research, the best yields were established in accessions RK1 and RK2 (location Mostar), above 50%, and the lowest in accession PO1 (location Počitelj), less than 50%.

Conclusions

The highest values for fruit weight, peel weight and fruit width were determined in accession PNJ (location Stolac), and fruit height and weight of all arils for accession PB1 (location Stolac), while weight of 100 arils had the highest average value in accession RK1 (location Mostar). The lowest average values for fruit weight, fruit height, fruit width, peel weight, weight of all arils and weight of 100 arils were found in accession PO2 (location Počitelj). The properties of crown height, crown width, and peel thickness had the lowest average values in accession RK2 (location Mostar). For the properties fruit crown height and width, there was no significant difference between the two study years, which indicates that these properties are mostly genetically determined. It should be noted here that the environmental conditions for growth and development of wild pomegranate were favorable in both study years with the fact that the precipitation conditions were more favorable in 2014. It should also be noted that the year factor had a greater influence on pomometric properties of wild pomegranate than the location factor, as well as the fact that the studied locations did not significantly differ in values of climate indicators.

Abstract

This paper shows the results of two-year research (2013-2014) of the weed vegetation of the Lijevče polje area which includes four associations: *Panico-Galinsogetum parviflorae* Tüxen at Becker 1942, *Panico-Portulacetum oleraceae* Lozanovski 1962, *Cynodono-Sorghetum halepense* (Laban 1974) Kojić 1979 and *Erigerono-Setarietum glaucae* Šumatić 1997. Floristic-phytosociology researches were performed by the principles and methods of the Switzerland-French phytosociologic school on 61 localities from the area of municipalities Gradiška, Laktaši, Srbac and Kozarska Dubica in Nothern Bosnia and Herzegovina where 49 relevés were taken. Vegetation research included taking of relevés on test area of 100 m^2: space in row and between rows in orchard and vineyard, in grain crops and stubble from the whole area, root crops, and space between the rows. Relevés in orchards and vineyards on the territory of Lijevče polje were taken in neglected orchards and vineyards and in vineyards which are extensively processed and relevés in thick set crops and stubble were taken from parcels where herbicides were used, as well as from parcels where the application of herbicides was reduced. Also, relevés in root crops were taken in the same manner. Weed flora covered with four plant communities consists of 91 species. Results of correspondence analysis of all association shows similarity of stands association do not stand out subassociations. By projecting the plant communities on the mail components (Principal Component Analysis) and comparting them to the ecological indices (variables), it shows that *Panico-Galinsogetum parviflorae* depends on humidity the (F) and the chemical reaction (R), while *Panico-Portulacetum oleraceae* shows the dependence on the nutrients (N). Association *Cynodono-Sorghetum halepense* shows the dependence on the temperature (T) and the light (L). Association *Erigerono-Setarietum glaucae* is separated because it develops on the stubble.

Keywords*: weed vegetation, ecological indices, Lijevče polje*

Introduction

Weed flora and vegetation mostly depends of ecological conditions of the particular area, the kind of the crop and applied agrotehnical measurments (Shrestha *et al*., 2002, Barać and Garić, 2004). There are several data about weed vegetation of the particular parts of the Balkan Peninsula (Kojić *et al*., 1982; Hadač *et al*., 1997; Dujmović-Purgar and Hulina, 2004; Šilc, 2005; Kropáč, 2006).

The weed vegetation has not been thoroughly researched in the area of Bosnia and Herzegovina and Republika Srpska. In a study of weed vegetation of the Pannonian basin in the Republic of Srpska in row crop, Šumatić (1997) noted association *Panico-Galinsogetum parviglore* Tüxen et Becker 1942, which has distinguished *Panico-Galinsogetum ambrosiosum artemisifoliae* facies, and associations *Galeopsi-Calistegietum sepii* Stepić 1984 and *Erigerono-Setarietum glaucae* (new ass.) in small grains, which is the first serious study of weed vegetation in this area. Weeds in orchards also have been neglected until the research

Mitrić (2004). Kovačević (2008) has been doing research of the vegetation of weeds and vineyards in Bosnia and Herzegovina and found eight associations.
Studying of the weed vegetation in the area of Lijevce Polje is neglected. The last serious research of the vegetation of weed in Lijevce has been done by Kovačević (1956) where two associations are noted. In the grains society we have *Trifolium arvense-Scleranthus annuus* with 62 weed species in grains, and as far as root crops are concerned, there are 64 species under association of *Oxaleto-Chenopodietum polyspermi medioeuropeaneum*. The aim of the paper is to analyze the weed vegetation in the Lijevče polje area from the floristic, ecological and phyto-geographical aspects.

Material and methods

Floristic-phytosociology researches were performed by the principles and methods Braun-Blanquet (1964). The research includes 61 regions from the area of four municipalities (Gradiška, Laktaši, Srbac and Kozarska Dubica) in Bosnia and Herzegovina where 49 relevés were taken. Vegetation research in the field included taking of relevés on test area of 100 m^2: space in row and between rows in orchard and vineyard, in grain crops and stubble from the whole area, root crops, and space between the rows. Relevés in orchards and vineyards on the territory of Lijevče polje were taken in neglected orchards and vineyards and in vineyards which are extensively processed and relevés in thick set crops and stubble were taken from parcels where herbicides were used, as well as from parcels where the application of herbicides was reduced. Also, relevés in root crops were taken in the same manner.
Determination of the plant species was performed according to Josifović (1970), Domac (1994) and Javorka and Csapody (1979). Taxonomy and the nomenclature were given according to Josifović (1970). Ecological optimum for each weed species was determined according to Kojić *et al*. (1997). There are ecological indices for the soil humidity (F), chemical reaction of the soil (R), content of nitrogen in the soil (N), light (L) and temperature (T). Statistical processing of the data was dane by using the program BioDiversity pro (1998) and SPSS 21.0 (2013). Phytosociologic differentation of the associations included the numerical classification which was completed by corrresponence analysis (Sneth and Sokal, 1973).

Results and discussion

In order to have a better control of weeds in the agroecosystem, it is necessary to have knowledge about their floristic composition as well as the characteristics and dynamics of their communities in comparison with ecological conditions which dominate particular area (Kovačević *et al*., 2017). Based on the two-years long floristic-phytosociology research it can be concluded that the weed vegetation in Lijevče polje area consists of four communities.
Weed flora of four plant communities consists of 91 species. Species that have higher degree of presence (II-V) and higher cover value are shown in Table 1.

Table 1. Synoptic table of the plant communities in Lijevče polje area.

Legend:

*Pan-Gal-*Panico-Galinsogetum parviflorae*; Pan-Port-*Panico-Portulacetum oleraceae*; Cyn-Sorgh-*Cynodono-Sorghetum halepense*; Erig-Seta-*Erigerono-Setarietum glaucae* **DP-degree of presence (I-V), A (+,1,2,3,4,5)-abundance of the species

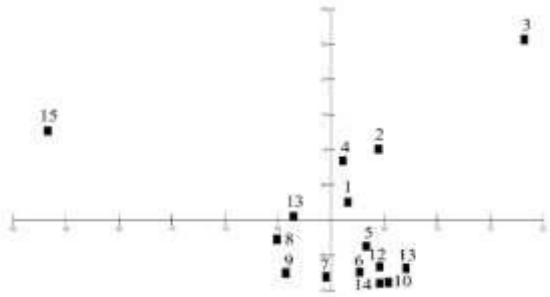
Ass. *Panico-Galinsogetum parvflore* Tüxen et Becker 1942 is widespread in row crops and growing crops (Šumatić 1997; Mitrić 2004; Kovačević *et al*. 2017). In the area subjected to research the association *Panico-Galinsogetum parvflore* Tüxen et Becker 1942 takes an important place in weed vegetation in Lijevče polje area. It can be found in orchards, vineyards, small grains and row crops. Results of correspondence analysis (Figure 1a) show certain similarities of stands association and any subassociations do not stand out. Stands 3 and 15 are singled out from other stands.

Ass. *Potrulacetum oleraceae* Lozanovski 1962 is firstly described in Macedonia. Kovačević *et al*. (2017) described this association in vineyards of Bosnia and Herzegovina. Stands of this association appear in various row crops but in growing crops, too. In weed vegetation of Lijevče polje area this association is row crops such as corn and watermelon and in orchards which are extensively farmed. Correspondent analysis shows a certain similarity of the floristic composition of association stands where stands 9 and 10 are at a distance from the

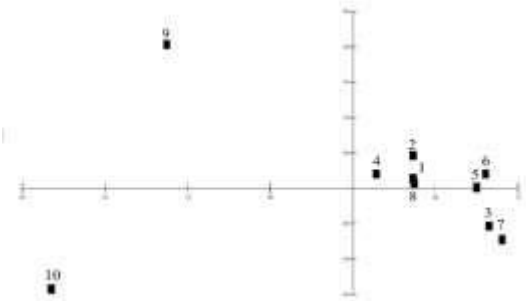
groups of stands in in a coordination diagram. (Figure 1b). This distance of stands is due to the fact that they were registered in the orchard, while others were registered in row crops and small grains.

Ass. *Cynodono-Sorghetum halepense* (Laban 1974) Kojić, 1979 was described in the most details in Kosovo (Kojić and Pejčinović 1982). Stands of association usually occur in row of orchards, as well as in row crops such as corn. In vineyards of Bosnia and Herzegovina this association was described by Kovačević *et al*. (2015). In Lijevče polje area the association is typically present in corn crop, soy crop, beans crop, and in row of orchards. Correspondent analysis showed similarity in terms of floristic features between the first group of stands under the numbers 1-8 and the second group numbered 9-13. Stands 9, 10 and 13 stand out from the rest (Figure 1c).

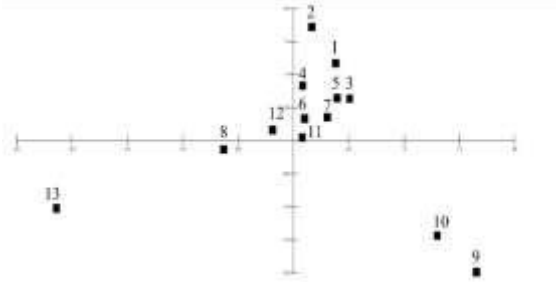
Ass. *Erigerono-Setarietum glauce* Šumatić 1997 was primarily described as the weed community of stubble in Semberija region, all the way to Doboj. Also, this association was described in vineyards of Bosnia and Herzegovina (Kovačević *et al*., 2017). In weed vegetation of Lijevče polje area this association is widespread on stubble, row crops (corn) and in orchards. Results of correspondent analysis confirm the similarity of the floristic composition. Stands 6 and 12 stand out from the other stands (Figure 1d). Stand 12 was registered in an orchard and is floristically richer than the stands registered in row crops.



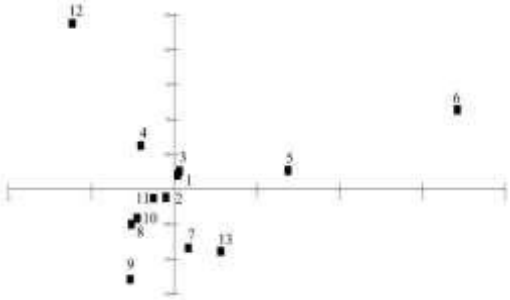
Panico-Galinsogetum parviflore (a)



Panico-Portulaceum oleraceae (b)



Cynodono-Sorghetum halepense (c)



Erigerono-Setarietum glauce (d)

Figure 1. The correspondence analysis of stands of four plant communities.

In terms of ecological relations between described plant communities, according to the ecological indices of the total floristic composition of each community and the established number and coverage of each species in the community, the statistical process of the data was undertaken. Starting from the correlation matrix of the average values of five ecological indices (F, R, N, L, T) for four communities described (Table 4, Table 5), and by applying the method PCA (Principal Component Analysis), the reduction of the beginning group of the changeable (ecological indices) is undertaken onto two main components which explain of the variability of the beginning the changeable.

Table 4. Matrix of Pearson's correlation coefficients of ecological indices.

Correlation	F	R	N	L	T
F	1.000	.906	.756	-.956	-.805
R	.906	1.000	.411	-.890	-.814
N	.756	.411	1.000	-.710	-.429
L	-.956	-.890	-.710	1.000	.619
T	-.805	-.814	-.429	.619	1.000

Table 5. Correlation of principal components with the initial variables.

Variables	Component	
	PC1	PC2
F	.252	.063
R	.232	-.479
N	.184	.923
L	-.239	-.162
T	-.209	.543

Biplot diagram (Figure 2) shows the ecological indices and it is given the projection of the some plant communities onto the main components (IBM SPSS, 2013). The sharp angles between the vectors show the positive correlation while the obtuse angle shows shows the negative correlation of the appropriate changables. So the values of the ecological indices F and R as well as N are positively correlated, and values of the indices L and T are negatively correlated.

Association *Cynodono-Sorghetum halepense* shows the dependence on the temperature (T) and the light (L), while association *Panico-Galinsogetum parviflorae* shows the dependence on the humidity (F) and the chemical reaction (R). Association *Panico-Portulacetum oleraceae* shows the dependence on nutrients (N), while association *Erigerono-Setarietum glaucae* is different because it grows on stubble.

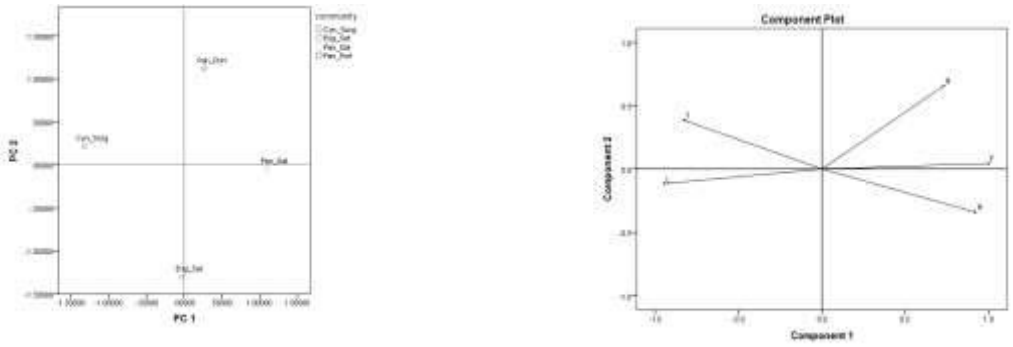


Figure 2. Biplot diagram of plant communities and ecological indices.

Conclusion

On the researched area, it was clarified that four weed plant communities that are characterized and clearly defined which is conditioned by reduced applying of the herbicides and generally weaker agronomic practices which reflected on the floristic difference since it is known that the intensive applying of the herbicides and the other agronomic practices leads to the significant changes of the structure and makes the biodiversity of the weed communities much poorer. This paper shows a comprehensive and fundamental research of weed flora in Lijevče polje area, considering that the latest research was conducted in 1956. Detailed

analysis of the weed vegetation should serve as a basis for successful planning and implementation of measures of weed control.

Abstract

Tartary buckwheat (*Fagopyrum tataricum* L., Gaertn) is an annual plant from Polygonaceae family. This species is mostly grown in Asia where it is used as a traditional food. In Bosnia and Herzegovina, Tartary buckwheat is grown sporadically and mostly in a mixture with Common buckwheat. In some plant species, increasing the planting density may be used to increase grain yield in crops. The aim of this study was to determine the impact of different planting densities on yield and total phenolic contents in kernel. During three study years (2011-2013), three different planting densities were used: 200, 300 and 400 seed per m^2. Experiment was set up by randomized block method in four repetitions at the village Donje Selo, near Ilijaš. The result showed that plant density did not have a significant effect on plant height, 1000-grain weight, hectoliter mass and phenol contents. Grain yields were significantly dependent on plant density and the year of the study. The lowest grain yield (1666 kg ha^{-1}) was recorded in the sowing variant with 200 seed per m^2 and the largest grain yield (2215 kg ha^{-1}) was recorded in sowing variant with 400 seed per m^2. Phenol contents in kernels depended on years of investigation and ranged from 1.07 to 13.94 mg g^{-1}.

Keywords: *tartary buckwheat, plant density, yield, total phenolic.*

Introduction

Buckwheat is an annual plant and belongs to the family Poligonaceae, which includes two cultivated species: common buckwheat (*Fagopyrum esculentum*) and tartary buckwheat (*Fagopyrum tataricum*). In general, morphological characteristics and growing technology of tartary buckwheat are similar to common buckwheat, but there are some differences. Tartary buckwheat has many desirable characteristics such as higher seed yield, self-pollination ability, frost resistance, and overall plant vigor. Thanks to the chemical composition, grain of buckwheat is primarily used to obtain high quality flour. Unlike flour of wheat and other cereals, buckwheat's flour contains proteins with good balanced amino acids and have all of essential amino acids (Selimović et al., 2014). In addition to the grain, used to obtain different products, buckwheat recently became more popular due to the use of other plant parts (leaves and flowers) due to their positive impact on human health. Healing properties of buckwheat are derived from the content of the phenolic compounds. The routine has the highest representation of the total phenol. According to Golob et al. (2016) tartary buckwheat contains about a hundred times more rutin than common buckwheat. The ability of buckwheat to synthesize phenolic compounds has emerged as an evolutionary response to adverse conditions of success (Germ, 2004). Content of phenol in buckwheat depends on the species and the variety of buckwheat (Bystrická et al., 2010; Christa and Soral-Śmietana, 2008), altitude (Guo et al., 2001), location and weather conditions (Sakač et al., 2014 and Suzuki et al., 2005). It is believed that the use of buckwheat contributes to the alleviation or prevention of many today's common diseases.Consummation of buckwheat is considered to relieve and heal diseases such as diabetes (Kawa et al., 2003; Li et al., 2016), high blood pressure (Tomotake et al., 2001) and it has anticancer activity (Park and Park, 2004). Buckwheat is mainly produced in moderate climatic zones and in mountain regions. According to FAO data

(FAOStat, 2018), in 2016, it was cultivated on an area of 2.37 million hectares globally. In Bosnia and Herzegovina, Tatarary buckwheat is grown sporadically and mostly in a mixture with common buckwheat. According to 2018 data, B&H cultivation area of buckwheat is 1056 ha and its average yield is 1.07 t ha^{-1} (FAOStat, 2018). Generally, in the world, buckwheats sowing range per area unit ranges from 40 to 100 kg ha^{-1} and it depends on the way of sowing. Literature data is different when it comes to optimal number of plants per area unit. Researchers who worked with the plant density of buckwheat agreed that it significantly changed the yield and may also have an effect on the content of total phenols (Gavrić et al., 2016; Gadžo et al., 2007). In Bosnia and Herzegovina there is only a few scientific papers related to this type of research, thus the focus of this research has been set based on these facts. The aim of this study was to determine how different planting densities reflects on yield and total phenolic contents in kernel.

Material and Methods

Field experiments were conducted in 2011, 2012 and 2013 growing seasons in the village Donje Selo, near Ilijaš. Tartary buckwheat (*Fagopyrum tataricum*) originates from Luxembourg and it was used in this research. Factors of this experiment were three different planting densities: 200 (S1), 300 (S2) and 400 (S2) seed per m^2. Experiment was set up by randomized block method in four repetitions. The size of basic plot was 4,8 m^2. The seeds were sown when the soil temperature was10 ^oC and the sowing was done manually. During the vegetation weeds were removed manually. Plant height and yield were measured in the field. 1000-grain weight, hectoliter mass and phenol contents were determined at Laboratories of the Faculty of Agriculture and Food Science Sarajevo. The total phenolic contents of ethanolic extracts were measured using Folin Ciocalteau reagent as described by Bystrická et al. (2010). Statistical analyses were made using SPSS 22 software programs. The monthly average temperature and precipitation amount was monitored during the period of the research (2011-2013). Data from Meteorological station at Sokolac were used for weather condition analysis (Table 1). During the research period, especially during 2012, above average warm weather was recorded. In 2012, July was the hottest month with the temperature higher than a year-long average for 4.4°C. The temperature increase was accompanied by droughts, with small amounts of rain, especially during the summer when it was most needed for buckwheat. Drought was particularly pronounced during 2011 and 2012, during the period of flowering and grow of grain. The weather conditions in 2013 were more favorable compared to the other two years (2011 and 2012).

Table 1. Average monthly temperature and Amount of rainfall

	Month

Results and Discussion

The plant height is an important morphological characteristic that can effect on lodging crops and lead to loss of yield. The results of the research presented in Table 2 show that plant height has not been significantly dependent on years of research and plant density. During the first year of research (2011), buckwheat was higher for 11.3 cm. Higher plant height was probably caused by bigger amounts of rainfall at the beginning of this year. Similar results were obtained by Glamočlija et al. (2012), who recorded 8.2% lower plants at relatively unfavorable weather conditions (lack of rain) compared to those grown in favorable weather conditions. Similar observations have been also reported by many authors (Ikanović et al.,2013; Maletić and Jevđović, 2003).

Table 2. Plant height, 1000-grain weight and hectoliter mass

Plant density	**Plant height (cm)**				**1000-grain weight (g)**				**Hectoliter mass (kg)**		
	2011.	2012.	2013.	Average	2011.	2012.	2013.	Average	2012.	2013.	Average
S1	99.3	81.3	85.3	88.7^{ns}	17.4	15.8	15.5	16.2^{ns}	59.6	61.5	60.5^{ns}
S2	100.7	94.0	91.9	95.5^{ns}	17.7	15.6	15.2	16.1^{ns}	61.0	62.5	61.7^{ns}
S3	99.0	96.5	88.1	94.5^{ns}	17.6	12.1	15.2	15.0^{ns}	60.1	60.8	60.4^{ns}
Average	99.7^{ns}	90.6^{ns}	88.4^{ns}		17.6^{a}	14.5^{b}	15.3^{b}		60.2^{ns}	61.6^{ns}	

The 1000-grain weight, which is an indicator of grain yield, was significantly dependent on years of research. By observing years of research, the 1000-grain weight value ranged from 14.5 g (2012) to 17.6 g (2011). The lower 1000-grain weight, which has been noted in the second year of research (2012) was the result of lower percipitation levels. These results are similar to Alekseyeva et al. (2001). They found that different agro-ecological conditions in some years have a significant impact on this research feature. Considering sowing variants, the highest value of 1000 grain weight was recorded in S1 variant (16.2 g) and the lowest was in S3 variant (15.0 g). Observed plant density factor over the years of research statistically did not show significant effect on the 1000-grain weight, but it had a negative impact on its value. Hectoliter mass, which is the first indicator of grain quality ranged from 59.6 to 62.5 kg. Difference in hectoliter mass was under the influence of plant density and the years of research were random, which was not statistically significant.

Table 3. Grain yield and Phenol contents

Plant density	**Yield (kg ha^{-1})**				**Phenol contents (mg GAE g^{-1})**			
	2011.	2012.	2013.	Average	2011.	2012.	2013.	*Average*
S1	1308.0	1420.2	2272.5	1666.9^{b}	1.17	13.94	1.46	5.52^{ns}
S2	1722.7	1959.0	2242.7	1974.8^{ab}	1.09	12.52	1.49	5.03^{ns}
S3	2317.7	1862.2	2465.0	2163.6^{a}	1.07	9.24	1.51	3.94^{ns}
Average	1515.4^{b}	1747.1^{b}	2326.7^{a}		1.11^{b}	11.90^{a}	1.49^{b}	

Observing the results from Table 3, it can be concluded that yield significantly depended on the plant density and the year of research. Grain yield was in a positive relation with the sown density. Average grain yield in the S1 variant was 1666.9 kg ha^{-1}, which increased the plant density to 1974.8 (S2) and to 2163.6 kg ha^{1} (S3). With relative indicators, yield increase was 15.6% (S2) and 22.9% (S3). A similar effect of sowing density was observed in all years of

research. Many researchers have also reported higher grain yield at higher planting densities (Gavrić et al., 2017; Thakuria and Gogo, 2000; Singh and Arya, 1996).

This study showed that plant density increase had a positive effect on yield. However, sometimes, an increase in plant density can cause reduction of yield. Gadžo et al. (2007) and Vilcāns et al. (2013) found that by increasing the sowing density reduced the yield. They concluded that the higher planting density leads to lodging and then reduces yield.

In this work, significant yield variations also have been recorded for the years of research. The highest average yield was recorded in 2013 (2326.7 kg ha^{1}) and it was significantly higher than the yield in 2011 (1515.4 kg ha^{1}) and in 2012 (1747.1 kg ha^{1}). Reason why buckwheat achieved the highest yield in 2013 is due to relatively favorable weather conditions. Many studies have shown similar effects years of research on grain yield during the years of research (Glazova, 1998; Gavrić and Gadžo, 2011; Popović et al., 2014).

The results of this research shown in Table 3 show that the content of phenol depended on the years of research. During 2012 (11.9 mg GAE g^{-1} SM), all plant density variants had a high content of phenol and it was about ten times higher than in 2011 (1.11 mg GAE g^{-1} SM). High content was recorded in the year with higher average monthly temperature, and based on this, it can be concluded that the weather conditions are the cause of those differences. Lumingkewas et al. (2015) and Kreft et al. (2013) also concluded that temperature and humidity influenced phenol contents. The three-year average shows (Table 2) that total phenol contents did not significantly depend on plant density, but there are some differences. The lowest content of phenols (3,94 mg GAE g^{-1}) was recorded in S3 variant and the largest content (5.52 mg GAE g^{-1}) was recorded in S1 variant.

Conclusions

According to the presented results of the research, effects of plant density on yield and total phenolic contents of tartary buckwheat during the seasons of 2011, 2012 and 2014, the following conclusions can be reached:

- plant height, 1000-grain weight, hectoliter mass and phenol contents demonstrated no significant changes under the influence of plant density, but they depended on the year of research;
- the grain yield significantly depended on plant density and the year of research;
- the largest grain yield (2215 kg ha^{-1}) was recorded in sowing variant with 400 seed per m^{2};
- phenol contents in kernels depended on years of research;
- high content of phenols was recorded in the year with relatively unfavorable weather conditions.

Abstract

A field experiment was conducted during 2016-2018 growing season on the experimental field of the Crop Science Department at the Agricultural University of Plovdiv (Bulgaria). The experiment was arranged using the block method as split plot in three replications and plot size of 10 m^2. Comparative assessment of the biological productivity of the tested Trismart, Musala and Kolorit (standard) varieties was made between the variants with application of PGRs under the action of lower and higher fertilizer rate. The foliar application of the PGRs followed in BBCH 31. During the vegetation of triticale, fresh plants were taken at stages: tillering-leaves, spike emergence-leaves, stem, spikes, maturity- straw, spikes, grains, glumes. The results from the study showed, that the effect of the mineral fertilizer at stage steam elongation on the biomass accumulation of triticale was better expressed than the differences between the varieties. The lowest biological productivity at this growth stage during the years of the study was detected in all varieties treated with the lower fertilizer levels. The higher fertilizer level itself led to 7-8% increase of the dry biomass accumulation during the years of the study. Similar percentage increase was observed in the variants treated with higher fertilizer level in combination with the plant growth regulators. In the analysis of the varieties regarding the different fertilizer level, there were no differences in the organ distribution compared to the total biological yield and by all treatments the straw occupied the largest share, followed by the grain and glumes. The biological yield of triticale at maturity during the period 2016-2018 was mainly formed by the straw, whose share by the different treatments and varieties varied from 47.15 to 50.28 %.

Introduction

Cereals are worldwide the most important cultivated crops and account for the main sources of energy and protein in human and domesticated animal diets (Rajaram, 1995). The rising demand for food in developing countries due to the high population growth rates continues to be a significant problem worldwide. Many of the developing counties rely on the import of large quantities of cereal crops such as mainly wheat, rice, maize and barley to meet their food and feed grain needs (Curtis, 2002). In these countries an increase of the national cereal production can be achieved through increasing average yield per unit area or expanding the production area into more marginal lands (Mergoum et al., 2004). Under these environmental conditions triticale can be a viable alternative due to its ability to produce higher biomass and grain yield compared with other cereal over a wide range of soil and climatic conditions (Gulmezoglu et al., 2010; Hein and Waschl, 2015; Ion et al., 2015; Kurowski et al., 2013; Madic et al., 2015). Produced by crossing two different species - wheat and rye with the main goal to combine the superior agronomic performance and the end-use qualities of wheat with the stress tolerance and adaptability of rye, today triticale is cultivated on over than 4 million ha (FAO, 2016). With the aim to evaluate the influence of PRGs and different fertilization levels on the biomass accumulation of triticale varieties, a field experiment was conducted.

Material and Methods

In the period 2016-2018 a field experiment was set on the experimental field of the Crop Science Department at the Agricultural University of Plovdiv, Bulgaria. Three triticale varieties were used - the standard Kolorit, Musala and Trismart. The experiment was arranged using the block method as split plot in three replications and plot size of 10 m^2 planted in the sowing rate of 550 germinated seeds after predecessor sunflower. The action of the PGRs Vitafer Algi (VA) and Vitafer Green (VG) and the untreated (NT) control variants was traced under two different fertilizer levels $N_6P_5K_2$ and $N_{12}P_{10}K_4$. The PGRs were applied in the beginning of stem elongation (BBCH 31). To achieve the aim of the study, during the vegetation of triticale, fresh plants were taken by stages as follows: tillering – leaves; spike emergence-leaves, stems, spikes; maturity – straw (leaves + stems), spikes, grains, glumes. The plants were taken from ¼ m^{-2}, divided into organs, dried to an absolutely dry mass and weighed. The soil on the experimental field of the Agricultural university - Plovdiv has been determined as alluvium, which based on the international classification of FAO belongs to the category of Mollic Fluvisols (Popova et al., 2012). The soil in this region has been developed on sandy-clay and sandy-gravel quaternary deposits, with power of the humus horizon of 20-40 cm. The results were analyzed using the software package IBM SPSS Statistics 22. In order to establish statistically significant differences between the variants, a dispersion analysis (ANOVA) was applied.

Results and discussion

The biomass accumulation at growth stage stem elongation was reported at the end of the period (Fig. 1). In this phase were not observed significant differences between the examined varieties, as by the untreated with growth regulators variants the lowest biomass accumulation of 242.84 kg da^{-1} in 2016 was determined in Musala variety and the highest in the standard – 260.84 kg da^{-1}, while in 2017 the lowest biomass was recorded in the standard (350.64 kg da^{-1}) and the highest in Trismart variety (421.36 kg da^{-1}). In all of the studied varieties the application of the regulators led to rise in the biomass accumulation with circa 8 % compared to the untreated variants. The growth stage spike emergence was characterized by the intensive linear growth of the vegetative organs, which significant increased the biomass accumulation of the varieties. In Kolorit and Trismart varieties the biomass accumulation increase compared to the untreated with growth regulators variants varied between 6-7%, while in Musala variety the increase was 8 %, from 684.90 kg da^{-1} for the untreated to 788.09 kg da^{-1} for the treated with VA. In the second year as a result of the better climatic conditions the biomass accumulation of the untreated variants varied from 1065.25 kg da^{-1} in Trismart variety to 1137.68 kg da^{-1} in Musala variety, which is 6 % higher than the previous year. As a result of the application with VA in phase maturity the biomass accumulation rose with 192.56 kg da^{-1} in Kolorit variety, 145.30 kg da^{-1} in Musala variety and 136.56 kg da^{-1} in Trismart variety during the first year. Similar increase was observed as a result of the application of VG. In the second year Trismart variety reached the highest biomass accumulation of 1756 kg da^{-1} due to the VA application, while in Kolorit and Musala varieties the highest increase of respectively 1579.08 kg da^{-1} and 1691.73 kg da^{-1} was observed after the VG application.

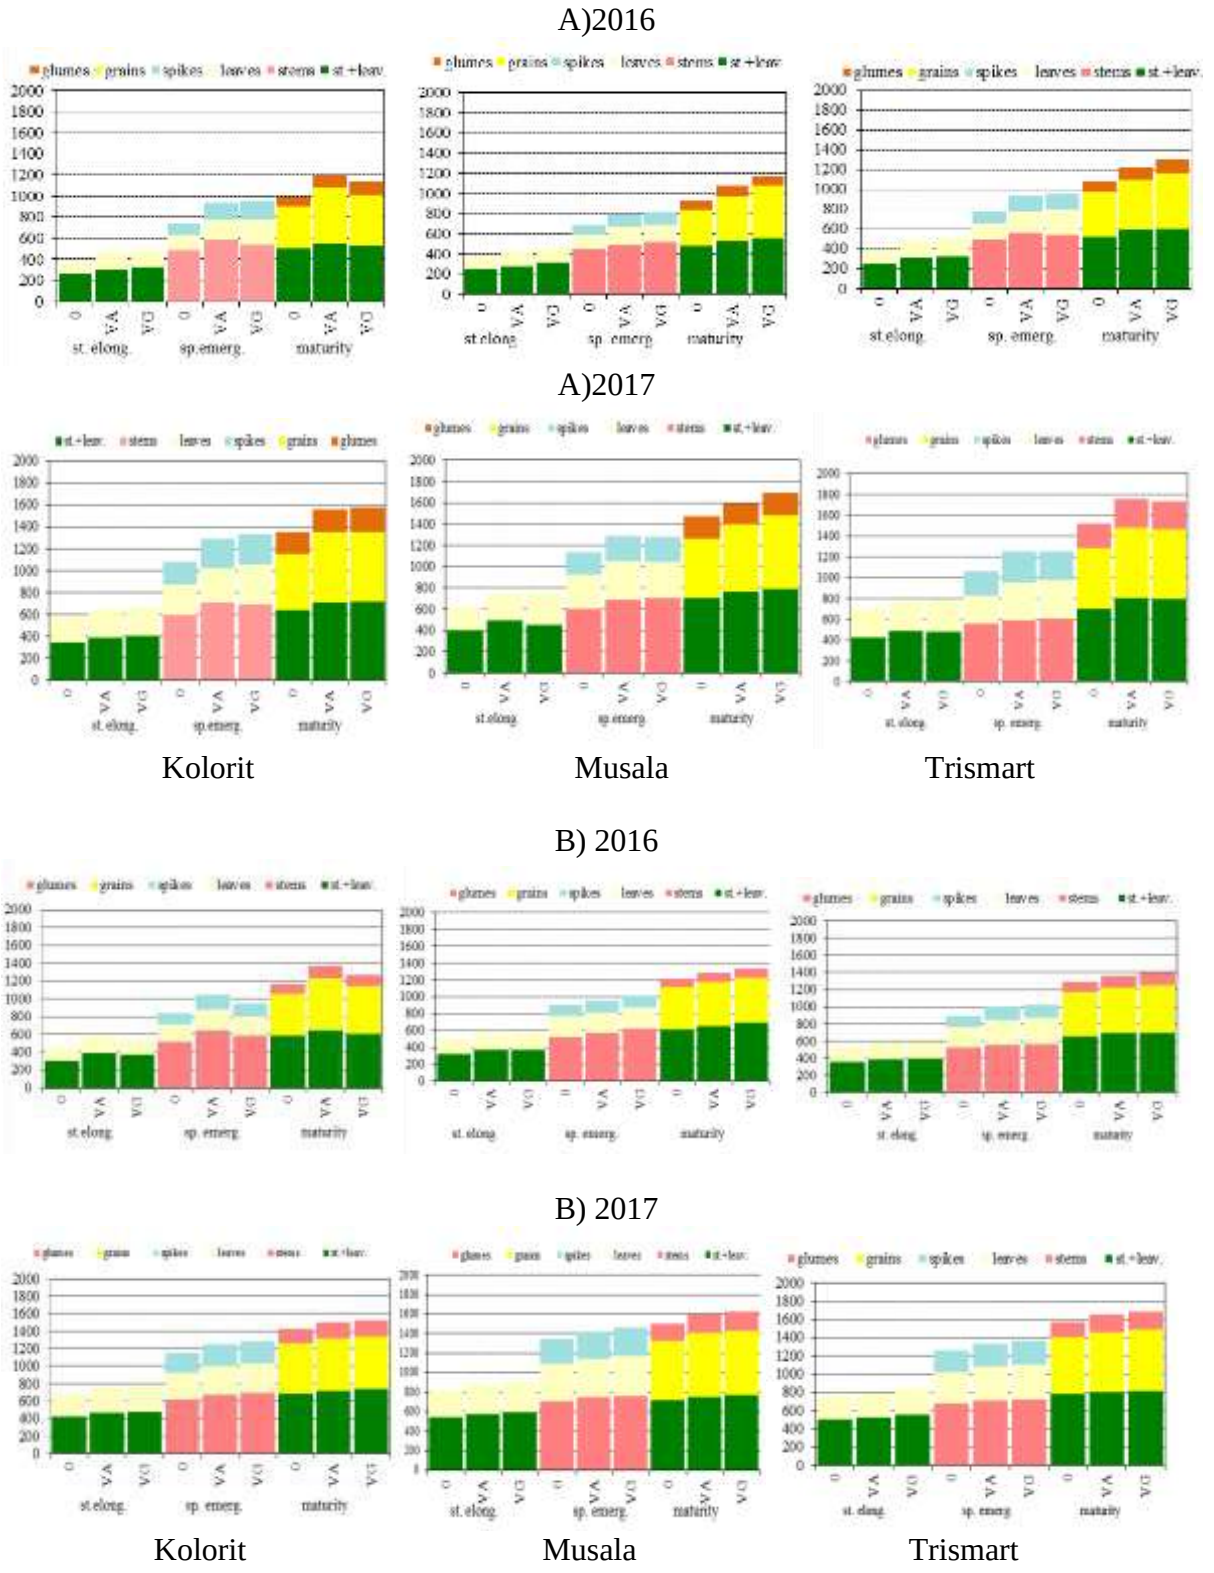

Figure 1. Dry biomass accumulation (A- lower fertilizer level; B-higher fertilizer level)

The results from the study showed, that the effect of the mineral fertilizer at stage steam elongation on the biomass accumulation of triticale was better expressed than the differences between the varieties. The higher fertilizer level itself led to 7-8% increase of the dry biomass accumulation during the years of the study. Similar percentage increase was observed in the variants treated with higher fertilizer level and the plant growth regulators, moreover at stage maturity during the first year of the study Trismart variety with yield of 1396.05 kg da^{-1} was

the most productive, than in Kolorit variety (1370.60 kg da^{-1}) and Musala variety (1334.01 kg da^{-1}). In the second year the tendency was the same and the combined treatment with the higher fertilizer level and VG led to the highest dry biomass accumulation in Trismart variety (1686.87 kg da^{-1}) and the lowest in Kolorit variety (1520.94 kg da^{-1}).

Table 1.Biomass yield in maturity average for the period 2016-2018 under higher fertilizer level, kg da^{-1}

Variety	Treatment	Biomass yield				% of the total yield		
		straw	grain	glumes	total	straw	grain	glumes

	VG	754.72^{c}	615.09^{c}	171.65^{c}	1541.46^{c}	49.01^{c}	39.94^{a}	11.05^{b}

*Values with the same letters do not differ significantly

The positive correlative interaction between the PGRs and fertilizer level, which generates yield increase was reported from many researches (Mac'kowiak et al., 2001; Starczewski, Bombik and Dopka, 2002; Wierzbowska, Sienkiewicz and Bowszys, 2010). The results indicated that the biomass formation of triticale as response of PGRs treatment would vary under the different fertilization levels.

Conclusion

At maturity the straw were with the largest share of the plant, followed by the grain and the spikes. However by the two fertilizer levels Trismart variety had the largest total biomass yield and the combined treatment with fertilizer and VG led to the highest percentage share of the grain (40.17%; 49.94%) compared to the Musala and the standard Kolorit varieties.

The foliar treatment with the both plant growth regulators can play an important role in triticale biomass yield formation. Plant treated with the PGRs under different fertilizer rates showed higher biomass accumulation compared to the control plants.

Abstract

Annona is a subtropical crop of an increasing popularity in Lebanon. Its cultivation is concentrated along the southern coast where climate conditions are the most suitable. Soil analysis at this location revealed a dominance of calcareous-clay soils poor in iron. The paper describes the results of an experiment which evaluated the effect of iron fertilization on the vegetative growth of three annonacultivars obtained by self- or cross-grafting of sugar apple (*Annona squamosa*L.: Sq) and Cherimoya (*Annona cherimoya* Mill.:Ch): Ch/Ch,Sq/Sqand Sq/Ch and cultivated in South Lebanon. Annona scions were grafted on rootstocks of 12 months age and data collection covered various vegetative indicators during on 1 year, 2 years and 3 years old plants. Iron (Fe) was provided to plants with irrigation water once per month starting from April till October in year 1, 2 and 3 with of 30g/plant. Results showed an improvement of vegetative growth in all cultivars compared to control plants during the three years with superiority for the cross-grafted cultivar (Sq/Ch). Iron-fertilized Sq/Ch and Ch/Chcultivars had the highestplant height (around 175cm), number of primary roots (around 42), length of primary roots (27cm), while the cultivar Sq/Ch developed the highest trunk diameter (4.1cm), diameter of primary roots (3cm), leaf biomass (142g) and freshand dry weights of roots (85g and149g respectively).Finally, iron fertilization improved the tolerance of annona plants to the present soil conditions of the southern coast allowing a better performance of plants during their juvenile stage.

Keywords: *South Lebanon, annona, grafting, iron fertilization.*

Introduction

Annonas is a genus of tropical fruit trees belonging the family Annonacea (Chatrou, 1999). Territorial expansion of the family Annonaceae is limited due to specific environmental and soil requirements (Encina *et al*., 2014). In fact, soil characters are extremely important for annona cultivation (Nakasone and Paull, 1998). In some regions of the world, Annonas are grown in calcareous soils. A common problem in these soils is an inadequate supply of soluble Fe which results in Fe deficiency in many crops (Korcak, 1987; Tagliavini *et al.,* 1995) resulting in leaf chlorosis and growth and yield suppression (Zouari *et al.,* 2001). Consequently, a fertilization program based on preliminary soil analysis (Pinto *et al*., 2005) is a prerequisite for excellent seedling growth and the production of good quality fruit (Pinto, 1975). An adequate supply of nutrients should be established targeting cultivated species (Fuehring, 1973). On annona, the amount of fertilizer applied varies with age and stage of growth. Thus, iron fertilization done in the second year should be done on soil analysis while the one of the third year on leaf analysis basis (Silva and Silva, 1997).

Vegetative propagation is the usual way of propagating annona (Heenkenda *et al.,* 2009). Annonas are easily propagated by grafting although the success of grafting varies among species and is influenced by the scion and rootstock compatibility. For instance, *A. cherimoya* roostock is compatible with its own scion as well as with the one of *A. squamosa*, however *A.*

squamosa rootstock is compatible with its own scion but has a low compatibility with the one of *A. cherimoya* (Pinto *et al.,* 2005). Cherimoya (*Annona cherimola* Mill.) is erect with an upright fast growth (Gonzalez *et al.,* 2012) reaching about 5-9 m and can tolerate a wide range of soil types with moderate fertility. Sugar apple (*Annona squamosa* L.) is normally smaller than cherimoya attaining heights of 3-7 m and grows best on fertile soils (Nakasone and Paull, 1998; Folorunso and Olorode, 2006; SCUC, 2006; Orwa *et al.,* 2009).

Lebanon is a coastal Mediterranean country characterized by various types of soils namely red and brown soils, sandy soils, heavily weathered fersialitic soils of volcanic origin (Chalak and Sabra, 2007). In Lebanon, Annonas are mainly cultivated in South Lebanon at an altitude of 0-200 meters above sea level (Yassine and Sassine, 2014) where calcareous soils are dominant (Louay, 1997). These soils are characterized by low content in organic matter and deficiency in nitrogen, zinc and iron (Fuehring, 1973).

Therefore, the current study was conducted in order to investigate the effect of iron application among various annona cultivars formed by self- or cross- grafting of sugar apple and cherimoya and cultivated in the calcareous soil of Southern Lebanese coast.

Materials and methods

Experimental site

The experimental orchard was situated in South Lebanon, at an altitude of 245 m.a.s.l (meters above sea level). Based on Brown (2003) soil at the orchard was identified as calcareous clay rich in phosphorus, nitrogen, sodium and calcium and poor in iron.

Treatments

Three annona cultivars were formed by self- or cross-grafting combinations of sugar apple (Sq)and cherimoya (Ch); self-grafted sugar apple (Sq-Sq), self-grafted cherimoya (Ch-Ch) and cross-grafted cultivar formed by sugar apple scion and cherimoya rootstock (Sq-Ch). Splice grafting was adopted and rootstocks were of 12 months old. Seedlings of each cultivar were transplanted with a distance of 4.5m between rows and 4m between plants into the experimental field. Iron (Fe) was applied monthly through fertigation starting from April with a dose of 30 g/plant. Vegetative growth was compared among plants grown in iron-fertilized soil (S1) and those grown with no iron fertilization (S2) over three consecutive years (year 1: 2012, year 2: 2013 and year 3: 2014).The experimental design was a Randomized Complete Block Design with 6 treatments and 30 replicates per treatment. Control consisted on 30 plants of each cultivar grown in S2.

Measurements

A destructive sampling was done at the end of vegetative growth of each experimental year on 10 plants per treatment including control. Randomly selected plants were subjected to various measurements like plant height (from the soil level till the top of the plant), trunk diameter (using sliding caliper), fresh weight of roots, number and length of primary roots (first ramification from the main root), diameter of main roots and dry weight of roots (obtained after oven drying till constant weight).

Data analysis

The effects of different factors: cultivar (Sq-Sq, Ch-Ch, Sq-Ch), iron fertilization (S1 and S2) and time (year 1, 2, 3) and their interactions on the averages of the measurements were analyzed using Factorial ANOVA. Data analysis consisted on means ± SE compared by Fisher's least-significant differences test (LSD) with a $P_{value}<0.05$ and was performed using STATISTICA10 Program.

Results and discussion

From the probabilities associated with Fisher statistics (Table 1) it was found that non-interactive effects of the factors time (year 1, 2, 3), Fe (iron fertilization) and cultivar (self- or

cross-grafting) were statistically (Pvalue<0.05) significant on all studied growth indicators. Moreover, interactive effects of factors "Time*Fe", "Fe*Cultivar" and "Time*Fe*Cultivar" were significant on averages of all indicators except plant height, length and diameter of primary roots. In addition, interactive effects of the factors "Time*Cultivar" was statistically significant on averages of all indicators except diameter of primary roots.

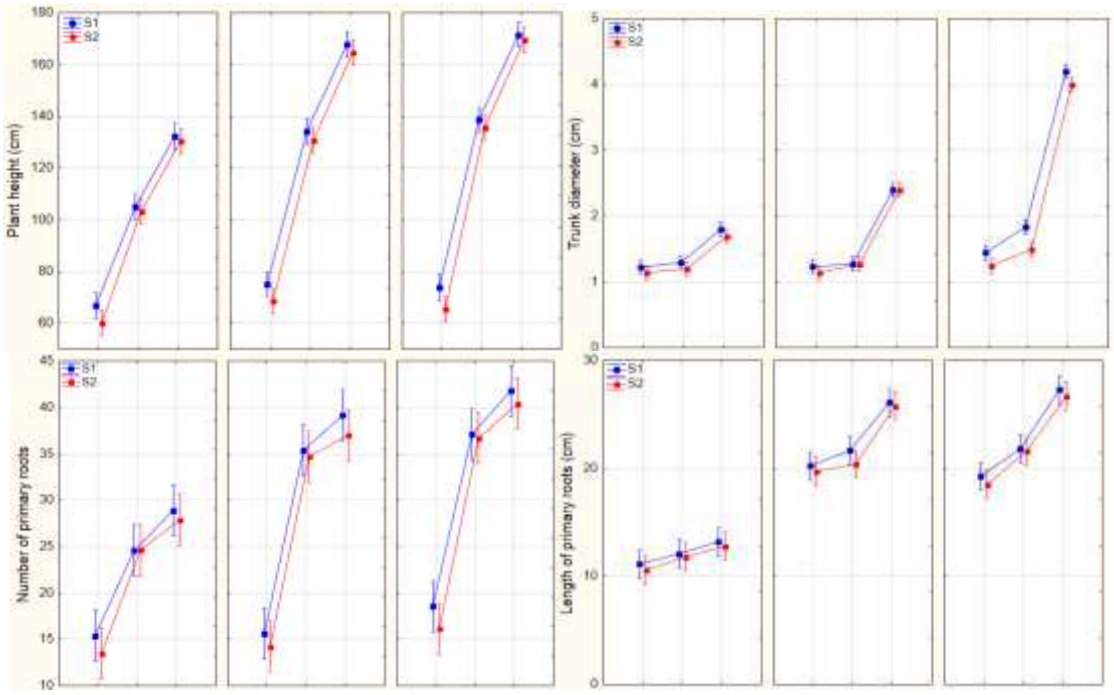
P.H: plant height, T.D: trunk diameter, N.P.R: number of primary roots, D.P.R: diameter of primary roots, F.W.L: fresh weight of leaves, F.W.R: fresh weight of roots, D.W.R: dry weight of roots

During the three experimental years, average plant height (Figure 1a) did not significantly differ among the cultivars Sq-Ch and Ch-Ch, while it was significantly higher in both cultivars compared to Sq-Sq in fertilized and non-fertilized plants (Sq-Ch/S1: 171 cm, Ch-Ch/S1: 167 cm, Sq-Sq/S1: 132 cm, Sq-Ch/S2: 169 cm, Ch-Ch/S2: 164 cm and Sq-Sq/S2: 130 cm). Differences in average trunk diameter (Figure 1b) as affected by iron fertilization were only observed during the third experimental year on the cultivar Sq-Ch where iron-fertilized plants of this cultivar had a significantly higher trunk diameter compared to non-fertilized ones (4.2 cm in Sq-Ch/S1 compared to 4 cm in Sq-Ch/S2). In year 1 and year 2, average trunk diameter did not differ among fertilized and non-fertilized plants of self-grafted cultivars (Sq-Sq and Ch-Ch). In addition, in year 3, superiority of this indicator was observed for iron-fertilized plants of Sq-Ch compared to all other treatments as well as to non-fertilized plants of the same cultivar. Root development was increased between year 1 and year 2 and did not significantly differ in year 3 in all plants. In year 1, average number of primary roots (Figure 1c) did not significantly differ among cultivars despite iron application, while in year 2 and year 3 average values of this trait were significantly higher in Ch-Ch and Sq-Ch compared to Sq-Sq. Iron application has only slightly improved number of primary roots in all cultivars (by 3.4 %, 5.6 % and 3.3 % for Sq-Sq, Ch-Ch and Sq-Ch respectively in year 3). Primary roots of self-grafted sugar apple (Sq-Sq) did not significantly grow in length with time with or without iron fertilization (11 cm in year 1, 12 cm in year 2, and 13 cm in year 3). In addition, average length of primary roots (Figure 1d) was higher in Ch-Ch and Sq-Ch compared to Sq-Sq despite the effects of time and iron application. Slight improvements in

length of primary roots were observed in treated plants of all cultivars following iron application. Best improvement was for self-grafted cherimoya in year 2 (21.6 cm and 20.4 cm in S1 and S2 respectively). Observations on the average diameter of the main root (Figure 1e) showed that cultivar (Sq-Ch) has developed the thickest main root among all cultivars (respectively of 3cm compared to 2cm and 1.7cm in Ch-Ch and Sq-Sq cultivars in year 3). Iron fertilization has positively affected this indicator in self-grafted cultivars (Sq-Sq/S1: 1.6 cm and Ch-Ch/S1: 1.8 cm compared to Sq-Sq/S2: 1.5 cm and Ch-Ch/S2: 1.7 cm) while it has negatively affected it in the cross-grafted cultivar (Sq-Ch/S1: 2.7 cm compared to Sq-Ch/S2: 2.9 in year 2). Moreover, iron application has significantly increased the average fresh weight of leaves in year 3 compared to control mainly in Sq-Ch and Ch-Ch (142g and 36g respectively in S1 compared to 90g and 31g in S2). Finally, the cross-grafted cultivar (Sq-Ch) had significantly the highest fresh (Figure 1f) and dry weights (Figure 1g) of roots despite iron application among all cultivars in year 1, 2 and 3. For instance, in year 3 the average fresh and dry weight of roots in S2 were respectively of 130g and 87g in Sq-Ch cultivar compared to 70g and 47g in Ch-Ch and 65g and 43g in Sq-Sq. However, the application of iron was significantly beneficial on both traits only in year 2 on the cross-grafted cultivar (Sq-Ch) (improvement by 15.7 % and 10.5 % in fresh and dry weight of roots respectively).



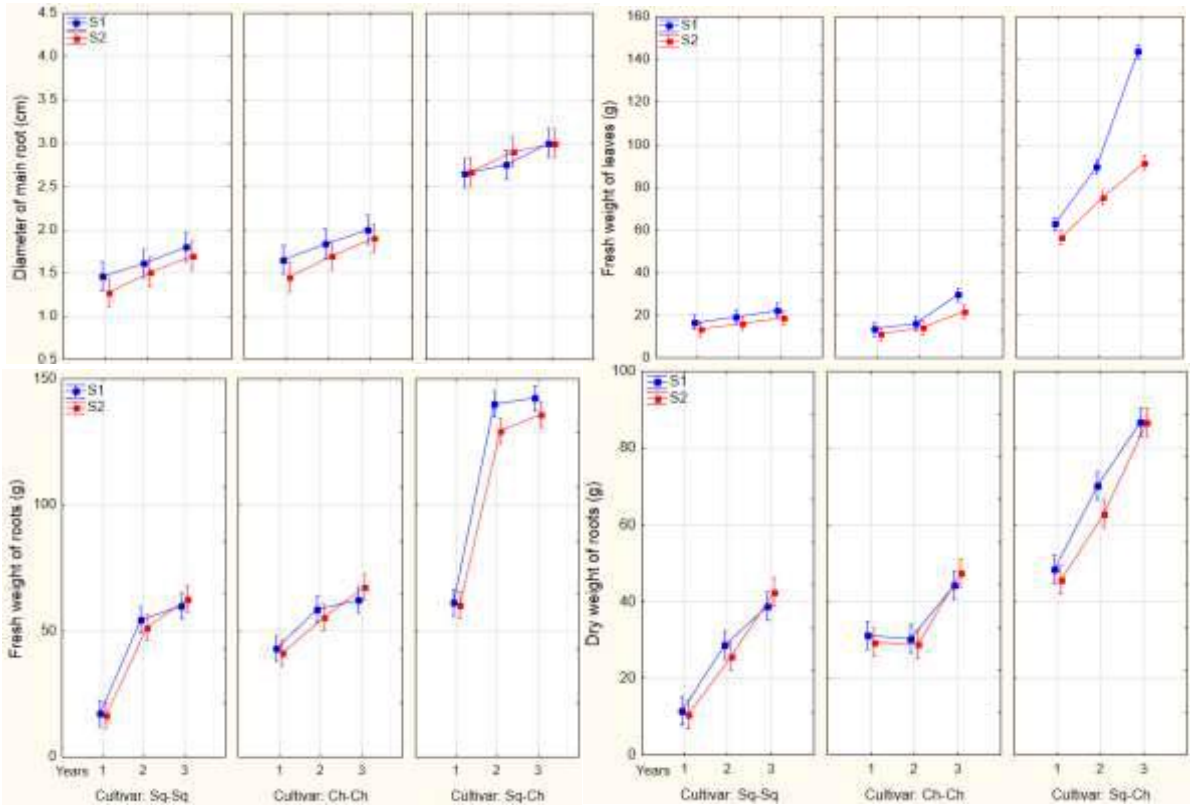


Figure 1: Averages (middle markers) and the 95% limits of confidence (±2 x standard Error: SE) (vertical bars) of various indicators

It is a well-known fact that there is a positive interaction between tree's canopy and its roots. According to Heenkenda *et al*. (2009) the growth and production characteristics of a grafted cultivar are influenced by both the rootstock and the scion; In fact cherimoya is a vigorous and prolific plant (Pinto *et al*., 2005) confirming the current results concerning self-grafted cultivar Ch-Ch plants height. Since the interaction between scion and rootstock is significant (Heenkenda *et al*., 2009), the maximum plant height was recorded for cherimoya grafted on to sugar apple rootstock. Besides, the highest trunk diameter was observed with the cross-grafted cultivar due to the positive scion-rootstock interaction which amplified vegetative growth of both cultivars. Indriyani and Karsinah (2011) have previously reported a better effect of cross-grafting compared to self-grafting on trunk diameter of *A. montana* Macf. x *A. muricata* L. cultivars. The well-developed and vigorous root system of Cherimoya was reflected by the optimal length and number of primary roots of self-grafted Ch-Ch and cross-grafted Sq-Ch cultivars. In fact, the grafting effect boosted the natural capacity of this rootstock leading to the formation of a more ramified root system with optimal root biomass. Consequently, this could have led to a better translocation of nutrients including iron leading to the formation of greater leaf biomass in cross-grafted cultivar. Similar findings were reported by Sebaaly *et al.* (2015) regarding cross-grafted cultivar Sq-Ch who found a positive interaction between sugar apple scion and cherimoya rootstock which improved the vegetative growth of plants grown in other type of soil.

On the other hand, iron application caused a slight improvement in the majority of indicators uniformly on all cultivars except the diameter of main root indicating a positive response of all plants to the newly available micro-nutrient. The most significant effect of iron fertilization was on leaf biomass and trunk diameter. This positive effect was similarly observed by Ojeda (2003) on annona plants grown in hydroponic system and by Bhanukar *et al.* (2018) and Abay and Pirlak (2016).

Conclusions

Combining cross-grafting and iron fertilization is an efficient method to optimize the vegetative growth of annonas in Lebanon. Since sugar apple and cherimoya are the most cultivated species in Lebanon, consequently the current work proposes a strategy to ameliorate the adaptation behavior of species to the dominant soil characteristics in South Lebanon.

PEA (*PISUM SATIVUM* L.) DIVERSITY IN BULGARIA AND A STRATEGY FOR ITS UTILIZATION

Siyka ANGELOVA, Mariya SABEVA*

Institute of Plant Genetic Resources "K. Malkov", Sadovo, Bulgaria
*Corresponding author: sabeva_m@abv.bg

Abstract

This paper presents the diversity of pea plant genetic resources (PGR) and carries out an analysis of the accumulated database for the National collection, supported by the Institute of Plant Genetic Resources (IPGR) in Sadovo, Bulgaria. Numerous varieties, populations, forms and breeding pea lines, diverse in phenotype, maturity, directions for use and productivity represent the plant materials that are studied and preserved in the IPGR. Special attention is given to the accessions of Bulgarian origin, as they take a central point of the studies conducted in the Institute. The share of the indigenous pea forms is about 12.4% (out of total number of accessions) as the oldest ones were collected during expeditions prior to 1950. Most of the preserved varieties are a result of long-standing selection and people's breeding with a goal for green mass. They are characterized by high winter resistance and rapid early spring growing (*M-9, P-1, №155, 35 [a], 37[a], Podobren Plovdivski, Pleven 10, Mir*). Other varieties from these accessions are bred for dry seed (*Pleven 4, Pikardi, Vessela*). The third ones are bred as a priority for lodging-resistance (*Tedi, Amitie*) and are adapted for direct harvesting (affilate forms). The typical green pea varieties for canning and freezing (*Uspeh, Plovdivska perla*) are stored at the Institute. A large number of old varieties and populations are actively grown in organic farms with a closed production cycle, in home gardens and in smaller farms. It should be mentioned that accessions with alien background are used as gene donors of valuable features for the breeding process or for evaluation of their potential and opportunities for utilization.

Keywords: *Plant Genetic Resources, Pisum sativum L., Organic farms, Breeding process, Utilization*

Introduction

The pea collection is the biggest of all grain legumes preserved in the National Gene Bank. The total number of accessions is 2560. About 25 % of pea collection is in long term conservation, 50 % in middle term conservation and 25 % are in working collection.

The pea collection contains samples from 30 countries. It provides great opportunities for using diverse plant material for scientific purposes, breeding improvement and for direct implementation and reonization (*Koeva et al, 1990; Angelova et al, 2001).* The accessions are grouped according to their important traits for the breeding program and for the farmers– earliness, winter hardiness, productivity, and protein content. (*IBPGR descriptors*)

The aim of this paper is to analyze pea collection, studied by stages for a long period of time.

Material and Methods

Field trials

The article represents the agrobiological characteristics of pea collection since 1986 *(Angelova,1986; Angelova, Ganeva, 1987*). The accessions have a set of valuable qualities (early maturing, lodging resistance etc.) and an economic assessment is made (*Angelova,1986; Angelova & Ganeva, 1987; Angelova, 2001; Angelova & Yancheva, 1996; Angelova & Sabeva, 2013).* According to the methodologies for preliminary study each variety accession is sown in an experimental field with size of two m^2 two times, while for

variety trials conducted in block method, the sowing is repeated four times as the size of the plot is ten m^2 with a relevant standard for comparison. The sowing of spring varieties is carried out as early as possible in the month of February or March. For the winter ones the sowing is in the period from 20^{th} to 30^{th} October.

Soil and Climatic Conditions

The trials are conducted on cinnamon forest soil on the experimental field at the Institute of Plant and Genetic Resources (IPGR) in Sadovo, Bulgaria. The town of Sadovo is situated in the Upper Thracian Lowland with an altitude of 141 meters and is characterized by transient continental climate. The winter is milder and the summer is hotter compared to Northern Bulgaria. The average annual temperature is 12,4°C the lowest one is in January and the highest in July. Sometimes the winter temperatures for two or three consecutive days drop down to minus 18°C and some days even below minus 20°C to be important for survival of winter pea varieties (*Boyadjieva & Stankova, 1990*). The amount of precipitation has its highest values in May with 47,5 mm and the lowest ones in September with 14,9 mm.

Results and Discussion

The National pea collection contains plant genetic resources of different origin, breeding level and botanical possessing. These resources provide an opportunity for improvement of breeding programs in different directions: for food, canning and fodder. The pea accessions are presented from the species of *Pisum sativum ssp. arvense, ssp. Sativum, ssp. hortense*, *ssp. transcaucasicum, ssp. asiaticum.*

The accessions of foreign origin include mainly varieties and breeding lines with a specific quality – gene donors for breeding material.

The plant material of Bulgarian origin occupies about 25%: indigenous landrace populations, old and new breeding varieties, breeding lines and mutant forms. The oldest ones were collected during expeditions prior to 1950. Most of the varieties are a result of long-standing selection and people's breeding with goal for green mass. They are highly winter resistant and early rapid growing in the spring.

The soil and climatic conditions in Bulgaria are favorable for pea growing. The biological characteristics allow to be grown as a spring and a winter crop. The first winter forage pea variety *Plovdivski podobren* is zoned in 1961. Later were bred the varieties *№ 30, Pleven 2, Pleven 5* that are similar in phenotype *to Plovdivski podobreno*. Since 1979 *Pleven10, Lozen 38, Lozen 517* are zoned. During the 1980s and 1990s, *Yubileyni*, *Mir and Vesela* are included on the variety list and still growing in Bulgaria (*Ganeva et al, 1985*; *Angelova & Ganeva, 1987; Angelova & Kalaphieva 2015*).

The accession number 37 from Knezha and accession number 63 from Kalofer could be considered as typical indigenous pea forms. The accession number E-548 from Silistra is added to the collection as a sample, brought by the international expedition in 1959. All of the materials from the plant genetic resources of Bulgarian origin are characterized by high winter resistability as the percentage of survived plants in winter conditions is from 80% up to 97% for a period of 15-20 years. Large parts of them are late varieties and in unfavorable climate conditions could not fulfill their biological potential. They could be used as gene donors for improving winter resistibility of plant (*Figure* 1) (*Ganeva et al, 1985; Angelova & Ganeva, 1987*). The winter varieties *Mir* and *Vessela* are widely used in organic farming in Bulgaria. They are plastic, rapidly growing and develop early in the spring, high productivity for green mass and seeds. These varieties early give yields and allow the next crop sowing to be done on the same plot. When damages from severe temperatures are observed on the central stem, the plants from all elaborated winter varieties react as form basal branches. Their pods very often completely compensate the productive opportunities of the central stem and give good yields *(Bastianelli et al., 1995; Decaux B, 1998).*

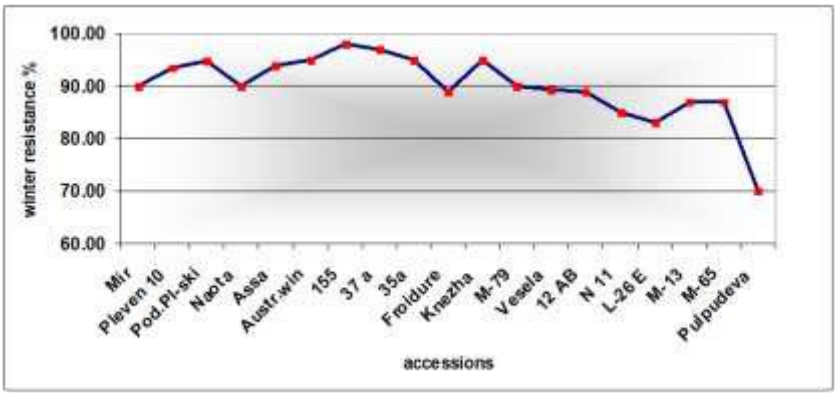

***fig. 1** Winter resistance accessions*

As a result of winter hardiness, the pea accessions are distributed in three groups: winter hardiness – 80% - 100%; low sensitivity – 70% - 80%; high sensitivity – 60% - 70% (*Angelova & Ganeva, 1987*). The main tendencies in the work with spring pea are focused on expanding and enriching the collection of early and middle early forms. They make the most of their biological potential in Bulgaria. The collection spring forms have a wide range of early ripeness.

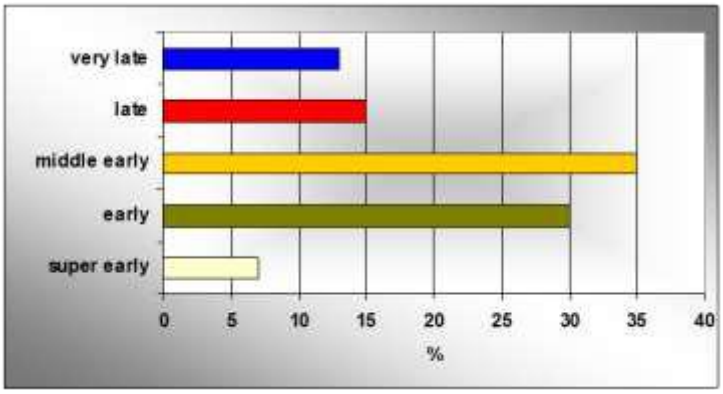

***fig 2.** Maturity of spring pea accessions*

Bulgarian weather conditions are characterized by early summer droughts and dry wind, typical for the Thracian lowland area; the duration of the vegetation period is of great importance. As for the supported collection of spring forms it is from 61 days up to 109 days. (*Angelova & Ganeva, 1987; Angelova S & Ch. Yancheva, 1996; Angelova & Kouzmova, 2001*). The spring varieties bred in Bulgaria are early and mid-early with relatively short vegetation period, good resistance to cold early spring temperatures. Their main requirement is the quality characteristic of the seed. In collaboration with the French National Institute for Agriculture Research (INRA) and in an application of mathematical methods and structural analysis, it has been found that the seed yield of winter pea is formed mainly from the first four productive floors, but more often after the third floor, while for the spring pea, the priority is from first and second floor. The recent breeding achievements in Bulgaria are the lodging resistant varieties from affilate type – *Amitie* and *Tedi, Pikardi* bred at the IPGR in a cooperation with INRA – France; and the highly productive varieties *Mishel* and *Sredez* bred at Dobrudzha Agricultural Institute in General Toshevo, Bulgaria are suitable for growing only in the Northern area of the country. Depending on the growing conditions, the genetic potential for high productivity is shown in different ways. Table 1 presents the statistical data for seed yields for winter and spring pea varieties grown in Bulgaria. During the entire fifteen-year research period, results show that the seed yield for winter pea varieties is from 270,5 kg/da up to 484,4 kg/da while for the spring ones it is from 268,5 kg/da up to 560,5 kg/da.

Table 1. Statistic data for yield in kg/da

	MIN	**MAX**	**MEAN**	**Std. Deviat.**	**V.C %**
Winter varieties					
№ 11	270,5	453,4	328,3	48,194	14,68
Mir	290,4	455,1	329,2	47,063	14,30
Vessela	298,4	484,4	352,3	55,104	15,64
L 12 AB	297,5	447,1	327,4	40,027	12,23
Spring varieties					
Amitie	268,5	560,5	407,1	81,213	19,95
Pikardy	279,5	531	401,1	74,636	18,61
Tedy	271,5	545	410,6	75,808	18,46

Although the yields vary by years, the results show that the varieties make their produce opportunities. All this is confirmed by the studies of (*Koeva et al. (1990)*; *Angelova & Kuouzmova, (2001)* that the temperature and the amount of precipitation affect to a great extent influence the quality characteristics of the accessions. For winter accessions, the variety influence is strongly manifested over the seed productivity while for the spring peas is better manifested the influence of the year (see *Figure* 5). In relation to crude protein (percentage absolute dry content) in the seed, the accessions are divided into four groups (see *Figur*e 6a).

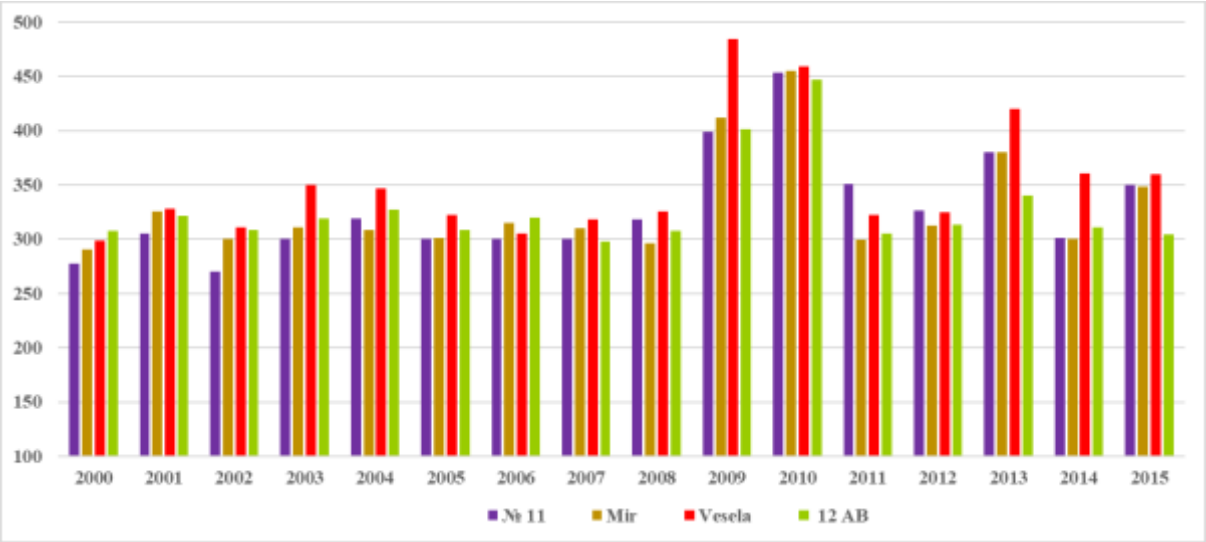

fig 3. *Seed yield from winter pea varieties*

The greater part of Bulgarian varieties fall into the second and third group from 23,1% to 26,0 % (*Angelova & Sabeva, 2008; Angelova & Sabeva, 2013*). The utilization of peas as a fodder plays an important role as alternative to make up for lack of protein during early the spring. The green mass content of crude protein (*see Fig 6b*) in the maturity phase (forming of lower 2-3 beans) is from 15% up to 22% (absolute dry substance) for the period from 10th until 30th of May depending on the variety's early ripening. There are no significant differences between the accessions from the same group. The varieties bred at the IPGR are widely used, and fall into the third group from 19% up to 22% *(Angelova & Sabeva, 2008; Angelova & Sabeva, 2013).*

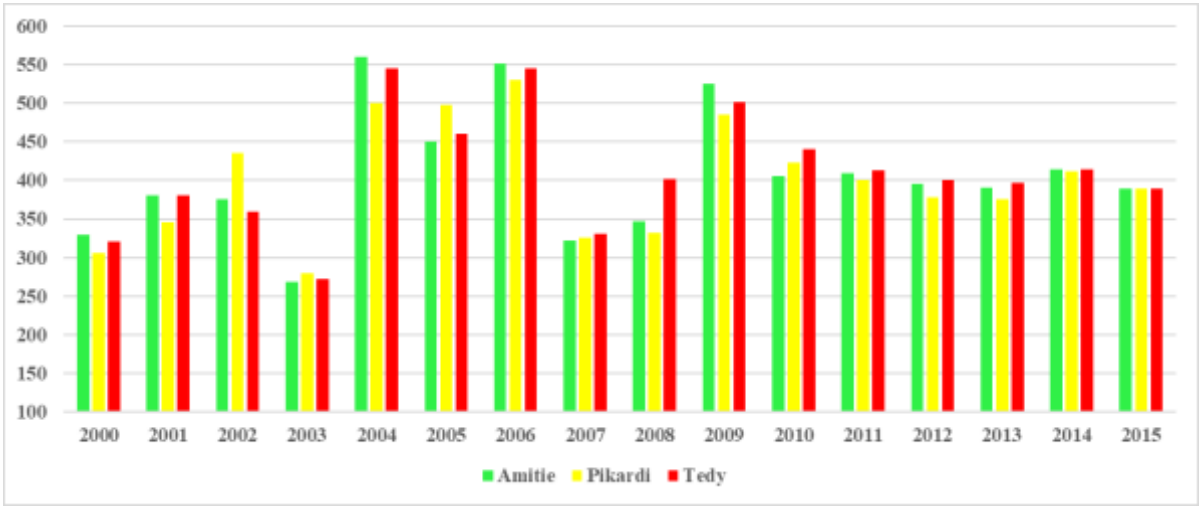

fig 4. *Seed yield from spring pea varieties*

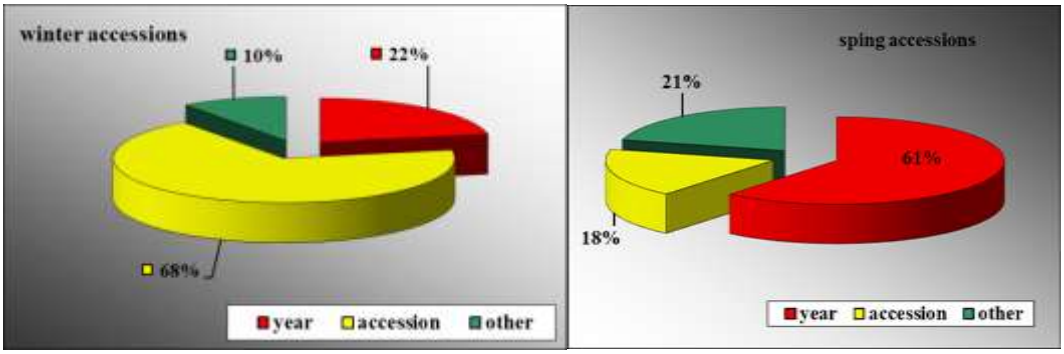

fig5. *Variety influence and year over the productivity*

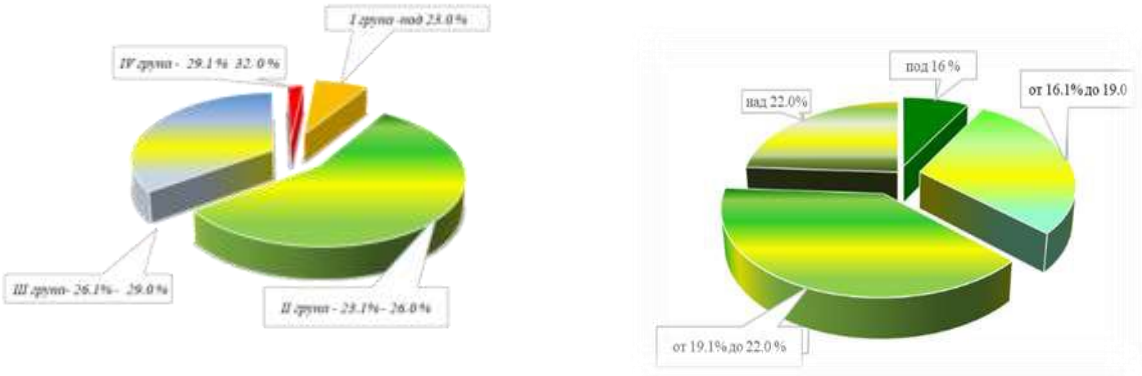

a b

fig.6 *Crude protein content in the dry seed and in the green mass*

The pea is used as a fodder and as a vegetable in Bulgaria. Besides for fresh consumption, it is a main source for the canning industry, mainly for preservation and freezing. There is a breeding program focused on satisfying the needs of customers at the Institute for Vegetable Crops Maritsa in Plovdiv, Bulgaria. The Bulgarian varieties *Ran I* and *Plovdivska perla* are the most preferred ones for growing in home gardens. From newly bred varieties *Musala* and *Iskar* are mostly used and are suitable for canning and preservation (*Angelova & Kalapchieva, 2015*). A large number from the old varieties and populations are used at organic farms with closed production cycle, in home gardens and in smaller farms. Natural habitats of *Pisum elatius* were identified during expeditions in the last years. Wider populations from the same genus are marked on the Northern and Southern Black sea coast, Kaliakra cape and Kamen Bryag. A seed material included in *ex situ* collection is also collected from the same habitats.

Conclusion

The proper and sustainable use of global and national collections from all crops leads to more efficient breeding activity. The modern collection of *Pisum sativum L*. needs a wide range of starting gene material to include more often indigenous germ plasma, primitive forms and wild species. A constant collection update is required to deepen and improve evaluation methods, necessary for successful and purposeful use, exchange and storage. By using the pea collection we created six pea varieties characterized by good earliness and high productivity. They are namely the following: *Mir*– winter resistant, forage type; *№ 11*- winter resistant; *Vessela*– winter resistant, dry pea; *Pikardi*– spring, dry pea; *Amitie* /af/- spring , dry pea; *Tedy* / af /– spring, dry pea. Winter varieties *Mir* and *Vessela* are used very often for green manure crops in organic farming.

Abstract

Cultivating spinach during autumn, as a sealing crop, has important economic and agro-ecological significance both through the yields achieved and by the more complete and rational utilization of the residual nutrients in the soil after harvesting the previous main crop. A field experiment with spinach variety Matador is conducted on the alluvial-meadow soil. The soil reaction (pH) is slightly acidic, humus content is low (1.33 %). The availability of mobile forms of N, P and K variants of an experiment in post-harvest predecessor are low mineral nitrogen and high P_2O_5 and K_2O. The study aimed to assess the post-effect of organic, mineral and mixed manure and mineral nutrition in the predecessor previous crop early potato with many treatments. Control variant without nutrition (T1), with organic (manure) (T2), with mineral (T3), and with mixed 50% manure-50% mineral nutrition (T4). The effect of treatments on growth, yield, quality of production and quality parameters in autumn growing spinach has studied. The experiment is a completely randomized design. The results indicate that the highest yield of spinach is obtained from the plants with post effect of the mineral nutrition. Plants which were grown after mineral nutrition has higher nitrogen, chlorophyll and nitrates contents. The dry matter content and total sugars are highest in the production of spinach after the previous crop fertilized with manure.

Key words: *organic nutrition, mineral nutrition, spinach, quality parameters.*

Introduction

A major challenge for modern horticulture is to reconcile productivity and sustainability of production systems and nutritional quality of food products. Nutritional quality is a highly complex trait due to both (i) the large number of individual properties which determine crop quality (i.e., concentration and bioavailability of essential and potentially toxic minerals, organic nutrients and accessory health factors) and (ii) the various factors which control them (i.e., genetic and exogenous factors, the latter either natural or man-made) (Wiesler, 2015). Provision of a sustainable environment in the soil by amending with organic inputs can improve the quality and acceptability of crop (Sharma and Agarwal, 2014). Autumn-winter crops can be an important reserve for compensation and increase the income of farmers. For optimum crop rotation schemes according to the requirements of good agricultural practice (GAP), using of leafy vegetable crops with short duration is recommended. Adequate crop for that is spinach, which can used as an indicator who expressed nutritional status of the soil. Leafy vegetables consist from huge diversity, spinach (*Spinacea oleracea* L.) a member of the *Chenopodiaceae* family. Usually spinach plant used as test crop in many agrochemical and ecological studies. (Botev, 2006; Dinev and Mitova, 2011; Mitova, *et al*., 2005; Mitova and Stancheva, 2003). Vegetative organs react quickly and appropriately to various biotic and abiotic effects. In previous studies, the performance of spinach crop was observed following the application of organic and inorganic fertilizers; It was found that the combination of both fertilizers was effective on increasing the mineralization rate of the organic matter (especially nitrate) (Anga,2001) as a result nitrate concentration of the spinach leaves increased.

Therefore, the objectives of this research are to determine post-effect of organic manures and chemical fertilizer on the growth, yield and quality of spinach.

Material and methods

Experiment is laid in experimental open field of IPAZR "N. Poushkarov " located in – Tsalapitsa village on alluvial meadow soil. Initial values of soil reaction (pH) (pH H_2O- 6.8; pH kcl- 6.0) and humus content (1.33%) characterized as slightly acidic soil with low humus content. It was done by the use of spinach cvs."Matador" sowing date in mid-September, after harvesting of early potato production. The production was finished on 10 November. An experiment was laid in Completely Randomized Design the options with 4 replications with the size of the experimental plot- 30 m^2. For the main crop (potatoes) in variants with 100% mineral fertilizer was added 20 kgN.da^{-1} as ammonium nitrate, 12 kg P_2O_5 da^{-1-} as triple superphosphate and 18 kg K_2O.da^{-1} as potassium sulphate.

By using manure which contain of 1.2% total nitrogen. Manure norm 20 kgN.da^{-1} was add with 1667 kg.da^{-1} manure.

In variant, four were added ½ of mineral fertilizer norms and manure. For experiment with spinach did not used any fertilizers. To understand the post effect of fertilization of the previous crop.

Variants of using fertilizers with soil reaction, and the content of nutrients after harvest the potatoes are present in Table 1.

Table 1: Soil agrochemical analysis in depth 0- 30 cm after harvesting of potatoes

Treatments	pH_{kcl}	NH_4-N	NO_3-N	P_2O_5	K_2O
(T1) without nutrition	6.5	10.63	5.70	17.63	24.32
(T2)100% manure	6.9	12.19	0.52	77.50	38.30
(T3)100% mineral fertilizer	6.7	7.52	13.48	21.91	33.35
(T4)with mixed 50% manure-50% mineral fertilization	6.9	4.41	3.63	30.72	28.50

The fresh weight of plants is determined by weight in kilograms per hectare. From the plant samples, after drying at 65˚C with a preliminary fixation, the dry substance (absolute dry matter%) was determined by weight. The total sugar content is determined refractometrically - (%) (Digital refractometer - 32 145). The nitrate content is determined on Merck's RQ flex plus 10 instrument. The content of plaster pigments in the fresh mass (mg.g-1) is determined by the Vernon method, 1960. The content of macroelements in the soil is determined by standard methodologies (Arinushkins, 1970), ammonium and nitrate nitrogen - colorimetric, movable forms of phosphorus and potassium by the method of P. Ivanov (1984).

In plants, total nitrogen was determined by the Keldahl method by decomposition with concentrated H_2SO_4 and 30% H_2O_2. The remaining macroelements were determined by "dry" burning in muffle furnaces and subsequent dissolution in 20% HCl, taking into account the atomic absorption spectrophotometer. The yield data is processed using the Statgraphics / Anova / Multifactor dispersion statistic package.

Results and discussion

The optimum growth and development of plants depend not only on the balanced absorption of nutrients. Their presence in the soil is readily available in readily accessible and digestible forms. External factors also influence the vegetation, which in certain situations can compromise production. Spinach is particularly sensitive to high acidity. The optimum soil pH should be 6.2 to 6.9 (Genkova, 2009). It can be seen (Table 1) that soil acidity is appropriate for the development of spinach. In all embodiments, the mineral nitrogen content

is low, and in the moveable form of phosphorus and potassium-rich forms. The particularly high content of P_2O_5 and K_2O in the soil is the manure variant with manure.
The yield data shows a significantly lower yield in the control variant compared to the plants suffering from the effects of using different fertilizers. It can be assumed that the yield from the non-treated plants should be comparable to the other yields. The reason for the low yield of the untreated variant, despite the fact that the nutrient content is close to that of the other variants, could be the highest density of weeds and the attack of diseases that occurred in the cultivation of the previous potato crop. Spinach from the untreated variant develops slowly, the formed leaves are small, and the plants prematurely shoot (Fig.1)

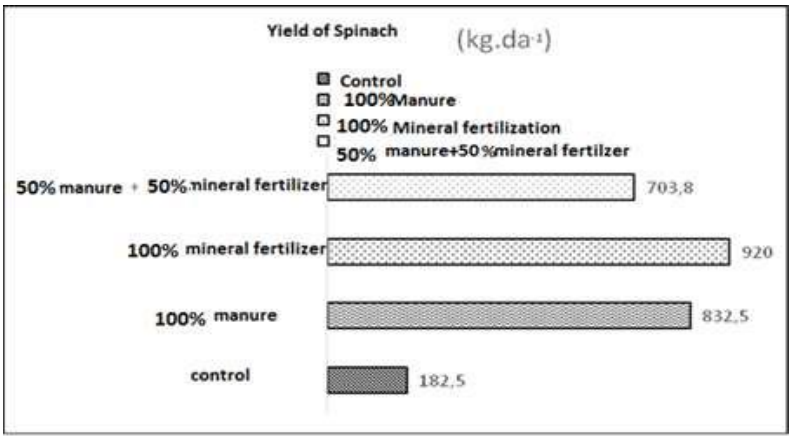

Fig.1: Yield of spinach after treatments Kg/da

The yields obtained in the study are significantly lower than those reported in the literature (Boteva Hr .. 2006, Genkova, 2009, Mitova et al., 2005; Rankov et al., 1994) in fertilization with organic and mineral fertilizers. In this experiment its important to take into account the fact that the obtained yields are the result of the effect of the fertilization of the base crop. The highest yield of spinach in the experiment was obtained in the variant with the effect of mineral fertilization - 920 kg / da(35%), followed by manure variants - 832,5 kg / da(31%) and mixed fertilization - 703,8 kg / da(27%). Differences in yields are statistically satisfied.(Fig.2)

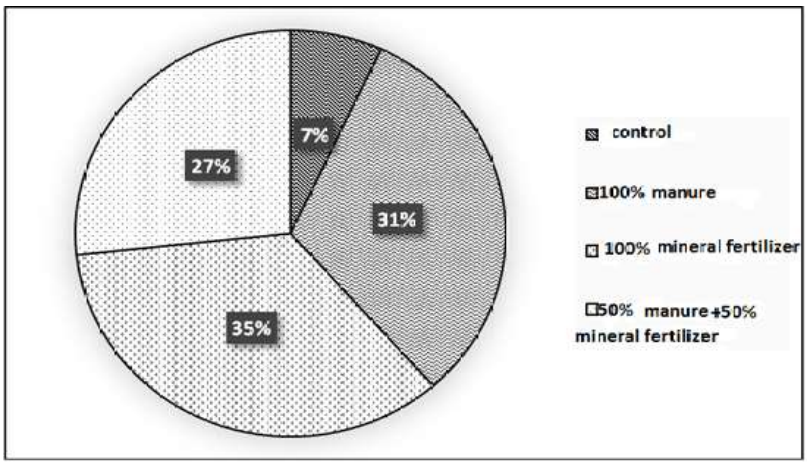

Fig.2: Yield of spinach in percentage %

The differences in yields at both statistical levels between control and fertilizer variants as well as between organic fertilizer plants and mixed and mineral fertilizers are statistically satisfied (Table 2).

Table 2: Statistical analyses of yield

Variants	***1. control***	***2. 100% manure***	***3. 100% mineral fertilizer***	***4. 50%manure+ 50%mineral fertilizer***
Average	703.8	920.0	832.5	182.5
Median	704.4	915.7	831.9	12.5
St Dev	18.11	15.80	17.71	42.5
F-Ratio- 485.37; P- Value- 0.000; (P≥95%)- 48.892; (P≥99%)- 71.142				

The total nitrogen content in the leaf mass varied between (2.0-3.9%) of the plants (Table 3) follows the yields obtained and is comparable to the cited values in the literature (Rankov et al., 2004; Mitova et al., 2015). High concentrations of phosphorus - 1.13%, potassium - 8.9% and calcium - 1.0% in plants with the effect of manure correspond to the high residual contents – these results showed reverse tendency in the movable forms of these elements the soil. The magnesium content in the leaves (0.11 - 0.63%) of all variants is lower than in other publications (Mitova et al., 2015).

Table 3: Content of nutrients (%) in leaves of spinach at end of the study.

Treatments	total N	P	K	Ca	Mg
(T1) without nutrition	2.0	0.9	6.1	0.67	0.11

(T4)with mixed 50% manure-50% mineral fertilization	2.6	0.96	7.5	0.77	0.34

Plastid pigments are involved in photosynthesis and play a role in plant growth and growth processes. The study of the composition and amount of pigments in plants under different conditions of development is of scientific and practical interest. Despite the unfavorable climatic conditions in the autumn-winter period, the applied fertilization (organic, mineral and organo-mineral) has a positive influence on the synthesis of plastid pigments (Table 4) and the content of chlorophylls in treated variants significantly higher values of Ch "a" + Ch "b" compared to the results obtained in other experiments (Mitova *et al*., 2015, Ratterman, 2006). The highest chlorophyll content in the experiment has plants grown after mineral fertilization - 15.8 mg%. According to some authors (Chinok, 1976), the normal ratio of Ch "a" / Ch "b" should be 3: 1. Bero *et al*., 2007 consider that the ratio of chlorophylls to 2- 3: 1 is constant and depends on a number of factors. In the present study, the nearest ratio of Ch "a" / Ch "b" to the optimal ratio is the 2.25: 1 ratio obtained after mineral fertilization.

Table. 4. Contents of plastid pigments in spinach leaves.

Treatments	Ch"a"	Ch"b"	Carotenoids	Ch"a"+Ch"b"	Ch"a"+Ch"b"
(T1) without nutrition	4.28	2.57	1.83	6.85	1.68
(T2)100% manure	9.04	5.90	2.88	14.94	1.53
(T3)100%mineral fertilizer	10.94	4.86	3.59	15.80	2.25
(T4)with mixed 50% manure- 50% mineral fertilization	7.89	3.57	3.31	11.46	2.21

Leafy vegetables contain relatively low amounts of dry matter, but they are characterized by a high content of vitamins and nitrates (Mitova *et al*., 2005, Mihov *et al*., 1980, Shaban *et al*., 2014). The dry substance is a relatively stable and genetically determined substance. While in fruity vegetable crops its content is lower, in leaf vegetables, in the case of spinach, the dry

matter levels are between 11.4 and 12.15% and are comparable to those of other spinach studies (Mitova *et al*., 2015). The highest levels of absolute dry matter are in the plants grown after treated with manure (Table 5), and for the other variants the differences in dry matter values are insignificant. In the Peev research, 1985, it proves that the sugar content correlates well with that of the dry matter. In this experiment, there is a similar positive relationship between the cited indicators. The foliar fresh weight of plants grown after fertilization with manure has the highest content not only of dry matter, but also of total sugars - 9.3%.

Table 5: Quality parameters of spinach production.

Variants	Absolute dry matter (%)	Total sugars (%)	Nitrate ($mg.кg^{-1}$)
1.control	11.40	5.8	76.23
2.100% manure	12.15	9.3	95.68
3.100% mineral fertilizer	11.95	7.4	176.49
4.50%manure+50%mineral fertilizer	11.85	5.2	79.21
F-Ratio	*0,95*	*149,74*	*92,38*
P- Value-	*0,450*	*0,000*	*0,000*
(P≥95%)	*1,060*	*0,489*	*16,006*
(P≥99%)	*1,543*	*0,712*	*23,289*

The accumulation of nitrates in the production of foliar vegetable crops is genetically predetermined (Genkova, 2009; Stoyanov, 1997; Afaf Ghaleb Hafiz Abu-Dayeh, 2006; Mitova and Stancheva, 2003; Rankov *et al*., 1994). The control of maximum permissible quantities of contaminants in the food is implemented by Ordinance of MAF-31 of 29.07.2004. For spinach, the limit value for nitrate in production harvested in the autumn-winter period is 3000 mg / kg. Experimental nitrate content ranges between 76.2 and 176.5 mg / kg of fresh weight, the highest concentration of nitrates being registered after mineral fertilization. The agrochemical analysis of soil samples from the variants (Table 6) with spinach after harvesting show a significant depletion of nutrients mainly of mineral nitrogen. In accordance with the low yields in the non-preferred embodiment, the residual ammonium and nitrate nitrogen contents are larger than in the other variants. The content of P_2O_5 and K_2O (Table 5) in the soil after the application of manure is still high at the end of the study.

Table 6: Agrochemical soil analyses 0- 30 cm at end of the experiment with spinach.

Treatments	$pH_{кcl}$	NH_4-N	NO_3-N	P_2O_5	K_2O
(T1) without nutrition	6.7	7.42	5.13	14.07	20.66
(T2)100% manure	7.1	6.74	2.00	64.92	34.13
(T3)100% mineral fertilizer	6.8	4.67	4.33	12.28	29.58
(T4)with mixed 50% manure-50% mineral fertilization	6.9	2.56	0.84	27.45	26.50

Conclusion

Cultivating spinach in autumn as a sub crop has important economic and agro-ecological significance both through the yields achieved and by the more sufficient and rational utilization of the residual nutrients in the soil after harvesting the main crop.

-The highest yield of spinach is obtained in the variant with the effect of the mineral fertilization.

-Plants grown after mineral fertilization have higher nitrogen, chlorophyll and nitrate content.

-The dry matter content and total sugars are highest in the production of spinach after a previous crop fertilized with manure.

Abstract

In all European regions, variations of temperatures have a cyclic character with a relatively regular change for the periods of active vegetation and dormancy. This regularity is valid and also observed on the large areas in the country. The unfavorable combination of high temperatures and low rainfall, as well as temperature changes at the end of winter and the beginning of spring season are factors which may have critical effects upon the development of orchards. Also important factor often responsible for establishing the warm or cold winter margin for many fruit trees and strongly affecting production near those margins is the amount of chilling available during the plants rest phase of its growth cycle. Chilling is generally considered to be that amount of time during the period the plant is in rest when the temperature is below 0^oC. Cherry (*Prunus avium* L.) and peach (*Persica vulgaris* Mill.) plants are the most widely spread orchards in Bulgaria. They can grow in all over the country, but the optimum results are got only in separate regions, where the meteorological conditions are most suitable for their growth and development. The aim of this paper is to establishing the empirical between the sums of negative temperatures measured in the period from of durable transitions of temperatures below 0^oC (chilling degree days) and the number of days with temperature below 0^oC. The other aim is to find empirical relation between date of durable transitions of temperatures above 10^oC to fruits ripening and the number of days with temperature above 10^oC.

Keywords: *cherry, peach, sum of temperatures, chilling*

Introduction

Since the middle of the last century numerous studies related to the assessment of climate and agro-climatic conditions and their changes during this period has been carried out. They show changing of hydro-thermal conditions connected with observing of extreme meteorological events as droughts, spring frosts, hails, floods etc. observed on the large areas in Europe and particularly in our country. Analysis of data for the last 30 years show that the phenophases of trees occurred earlier in spring. The duration of vegetation period increased with 8 - 13 days on average, over the 20^{th} century (Chmielewski, 2004; Menzel, 2003; Kazandjiev, 2008). High interest is assessment of change of terms for dates of stable transition of average daily temperatures across the different biological threshold as 0, 5, and 10°C during spring and autumn seasons, because they have important scientific and practical application and they show the limit between cold and warm part of the year and trace out duration of the vegetative season and winter dormancy period for different crops (Kazandjiev et al., 2011; Slavov and Moteva., 2007).The period with temperature below 0°C determined duration of dormancy period. The date of steady transition of the air temperature in spring from 5°C was accepted conditionally for the beginning of spring vegetation in orchard (Vandova, 1985; Herschkovich, 1984). In Bulgaria dates of steady transition of air temperatures across 5°C in spring and autumn determined duration of potential vegetative period (RVP). The duration of this period is in turn off 250-260 days, on average. Another index for thermal condition characterizing duration is the period with average daily temperature above 10°C is in turn denoted as the real vegetative period (RVP). This is the period for active vegetation, growth

and development of orchards and agricultural crops. The average duration of this period in Bulgaria is 200-220 days (Kazandjiev, 2008; Kazandjiev, 2011). Detail investigations on the occurrence of phenological stages and sum of temperatures for cherry and peach in Bulgaria was made also by Ganeva et al., (1974) and peach by Draganov et al., (1965) and Vandova et al., (1995, 2002). As regards on temperature conditions the investigations show that the average annual temperature during the period 1971-2000 compare with the period to the contemporary climate has risen by 1.5^{o}C, this increase is greater in Northern Bulgaria, but in South Bulgaria this trend was not observed. As a result the duration of potential vegetative period (PVP) is extended by 6 - 10 days (Kazandjiev and Slavov, 2006; Kazandjiev, 2011).

Material and Methods

Cherry (*Prunus avium* L.) and peach (*Persica vulgaris* Mill.) plants are the traditionally orchards in Bulgaria. The optimum results for the growing are got only in separate regions, where the meteorological conditions are most suitable for their growth and development. Data for this investigation was collected from agrometeorological and climatic archive of National Institute of Hydrology and Meteorology (NIMH). Long-term 1981-2010 daily and monthly meteorological data from 18 agrometeorological stations have been processed. Dates on the phenological development and more precisely the dates of fruit ripening for the cherry and peach trees during the period of 1980-2010 are presented for 18 meteorological stations. Dates of fruit ripening for the cherry and peach during the period of 1980-2010 are presented for 18 meteorological stations. Used stations were grouped by the similarity of agrometeorological conditions. Central North Bulgaria -Ruse; Northeast-Razgrad and Targovishte; Southeast-Yambol and Suvorovo; Central South-Plovdiv, Chirpan, Sadovo and Southwest- Kustendil and Blagoevgrad and eighth stations for peach Central North-Ruse; Northeast: Targovishte and Razgrad; Southeast-Yambol, Sliven and Suvorovo; Southwest-Petrich and Sandanski. All-time series was tested for homogeneity and was controlled statistical parameters - average, standard deviation and variation coefficient. The dates of steady transitions of temperatures and average dates occurrence of phenological stages ripening of fruits are present as time series of days which starting date 1th January, i.e. Julian days. For all 18 agrometeorological station are received the empirical relation between the sums of negative temperatures measured in the period from of transitions of temperatures below 0^{o}C (chilling degree days) and the number of days with temperature below 0^{o}C. We find to empirical relation between chilly degree days and date of durable transitions of temperatures above 10^{o}C to fruits ripening and the number of days with temperature above 10^{o}C.

Results and Discussion

At the beginning of investigation, we develop two types empirical models, describing the dependencies between the sums of negative temperatures measured in the period from of durable transition of temperatures below 0^{o}C (chilling degree days) and the number of days with temperature below 0^{o}C, fig. 1, and sum of active temperatures of date on durable transitions of temperatures above 10^{o}C to fruits ripening and the number of days with temperature above 10^{o}C for cherry trees (*Prunus avium* L.). The linear regressions models describes the relationship between chilling degree days and number of day with T<0^{o}C and sum of active temperatures of date on durable transitions of temperatures above 10^{o}C to fruits ripening and the number of days with temperature above 10^{o}C. Table 1and 2 show the average values of statistical parameters, as well as numeral values of the calculated equations, as average arithmetic values, standard deviation, mean absolute error (MAE) and variation coefficient.

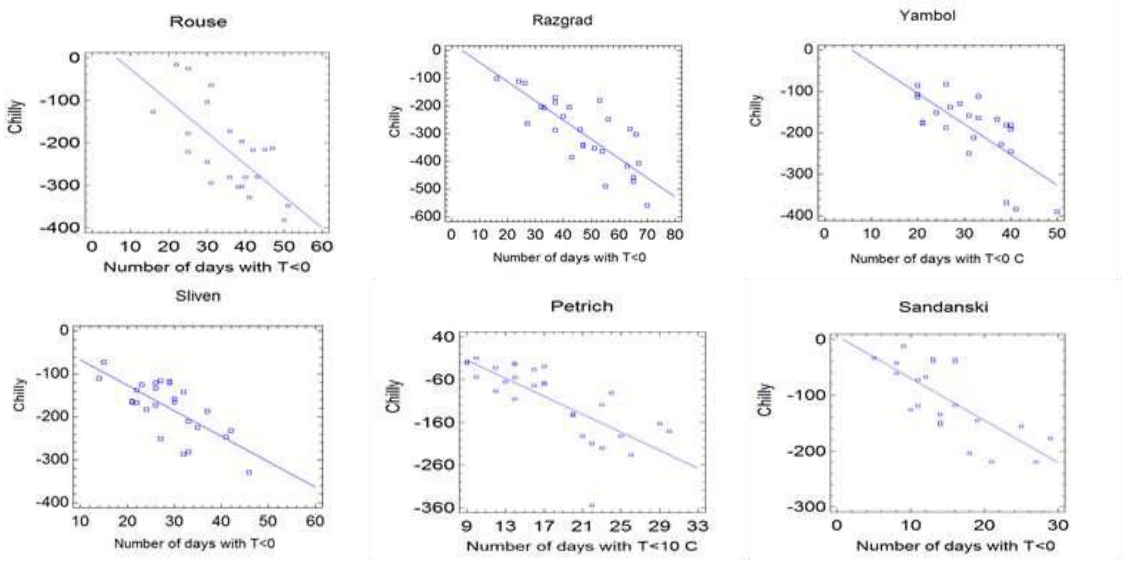
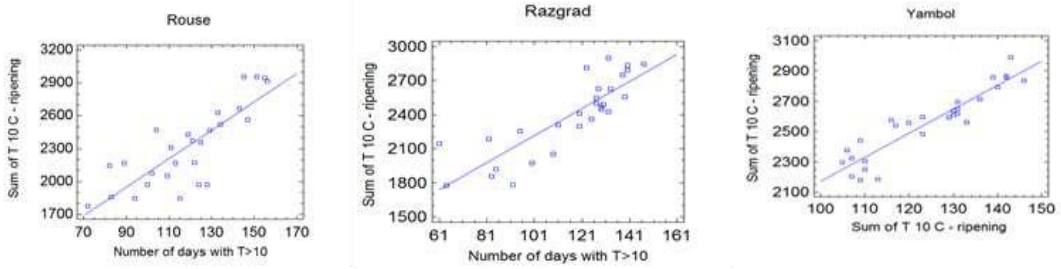
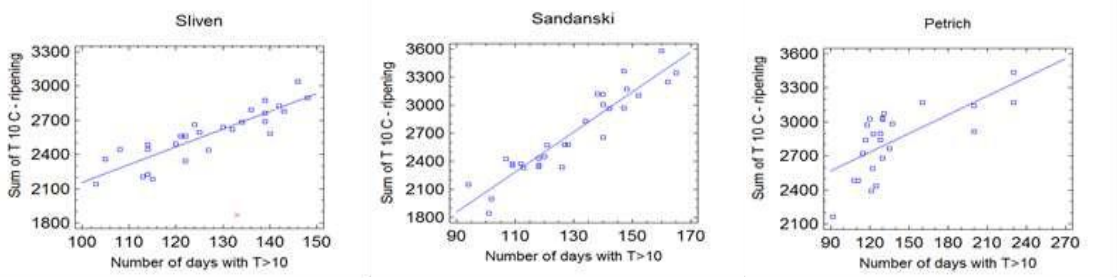
Figure 3. Dependence between chilling degree days and the number of days with temperature below 0°C for Peach trees



The last empirical model describes the relationship between sum of active temperatures of date on durable transitions of temperatures above 10°C to fruits ripening and the number of days with temperature above 10°C for peach trees, fig. 4.

Figure 4. Dependence between date of transitions of temperatures above 10°C to fruits ripening and the number of days with temperature above 10°C for peach trees.





Conclusion

We presented the empirical relations between the sums of negative temperatures measured in the period from of durable transitions of temperatures below 0°C (chilling degree days) and the number of days with temperature below 0°C during the winter dormancy period. Also we find empirical relation between date of durable transitions of temperatures above 10°C to fruits ripening and the number of days with temperature above 10°C during the active vegetation period. The sufficient number of events entailing regression equations, the relatively high values of the correlation index and immaterial equation errors give to recommend that dependencies are useful in agrometeorological practice.

THE EFFECT OF PGRs AND DIFFERENT FERTILIZATION LEVELS ON THE DRY MATTER FORMATION AND PHENOLOGICAL DEVELOPMENT OF TRITICALE VARIETIES

Rumyana GEORGIEVA*, Hristofor KIRCHEV

Faculty of Agronomy, Agricultural University, Plovdiv, Bulgaria

Abstract

The biologically active substances known as plant growth regulators (PGRs) are steadily gaining popularity, because they are harmless and ecologically friendly. Their application is not only easy and economically profitable, but also improves the action of the fertilizers, the mineral balance of the plant and leads to yield increase. In order to establish whether the PGRs would influence the phenological development of triticale, a biennial field experiment (2016-2018) was carried out on the experimental field of the Crop Science Department at the Agricultural University of Plovdiv using the block method in three replications, with plot size of 10 m^2. The action of the PGRs Vitafer Algi and Vitafer Green on three triticale varieties (Trismart, Musala and Kolorit (standard)) was conducted under two different fertilizer levels $N_6P_5K_2$ and $N_{12}P_{10}K_4$. The PGRs were applied in the beginning of stem elongation (BBCH 31). The results showed that the both PGRs treatments combined with higher fertilizer levels increased the specific growth rate and dry matter accumulation of the tested plants compared to the untreated variants and the variants treated with lower fertilization rates in combination with PGRs. The beneficial interactive effects of PGRs and fertilization levels on the phenological development of triticale are worthy to further exploration.

Keywords: *Dry matter, Fertilization, PGRs, Phenological development, Triticale*

Introduction

The importance of PGRs was first recognized in 1930s (Harms and Oplinger, 1988). Nowadays the plant growth regulators (PGRs) are widely used in the modern, high input cereal management, because of their large action spectrum. They are furthermore ecologically friendly, harmless, easy to apply and economically profitable. In their nature PGRs comprise a large group of endogenous and exogenous natural chemical compounds that can regulate plant growth in numerous ways (Rajala, 2003). When applicated PGRs can improve yields and their structural compounds (Kolev et al., 2011, Czapla et al., 2000), the mineral balance of the crop (Wierzbowska et al., 2010), the resistance to diseases (Osokina et al., 2015; Novik 1999) and serve as a prevention against lodging (Maciorowski, Stankowski and Piech 2000; Ilumae 2002). The effect of using such substances depends on many factors, e.g. a crop species, environmental conditions or fertilization (Czapla et al., 2007; Wierzbowska et al., 2010). The aim of this study was to evaluate the influence of PGRs and fertilization on the dry matter formation and phenological development in triticale.

Material and Methods

Field trial:

In order to achieve the aims of the investigation, a field experiment was set in the period 2016-2018 on the experimental field of the Crop Science Department at the Agricultural University of Plovdiv, Bulgaria. Three triticale varieties were used- the standard Kolorit, Musala and Trismart. The experiment consisted of a randomized complete block design after predecessor sunflower with three replications and plots of 10 m^2 planted in the sowing rate of 550 germinated seeds m^{-2}. The action of the PGRs Vitafer Algi (VA), Vitafer Green (VG) and

the untreated control variants (NT) was conducted under two different fertilizer levels $N_6P_5K_2$ and $N_{12}P_{10}K_4$. The PGRs were applied in the beginning of stem elongation (BBCH 31).
Estimation methods:
The beginning of the major phenological stages was identified according to Zadoks scale (1974): sowing (00- dry seed); sprung (10- first leaf through coleoptile); third leaf (13- 3 leaves unfolded); tillering (21- main shoot and 1 tiller); stem elongation (31- first node detectable); spike emergence (59- emergence of inflorescence completed); maturity (95- seed dormant). To establish the effect of the temperature and the precipitation conditions of the year, the sum of the active temperatures (above 5^0 C), Σ T act ^{0} C, the average temperature of the period (T aver. ^{0} C) and the sum of precipitation (mm) were calculated for each growth stage period. The dry matter formation and accumulation was determined according to Tretyakova' s (1982) formula for:

- dynamic of growth (g m^{-2} day^{-1}) = (B2-B1)/(D2-D1), where B2 is the dry matter determined at the end of the period; B1- the dry matter in the beginning of the period, D2- the date at the end of the period and D1- the date, when the period starts.

Soil and climate conditions:
According to Popova et al. (2012) the soil on the experimental field of the Agricultural university-Plovdiv has been determined as alluvium, which based on the international classification of FAO belongs to the category of Mollic Fluvisols. The soil in this region has been developed on sandy-clay and sandy-gravel quaternary deposits; with power of the humus horizon of 20-40 cm. Meteorological conditions are different during the years of the study.

Results and discussion

During the years of the study all varieties showed the same duration of the growth stage periods from sowing to tillering stage, due to the same temperature and precipitation requierments (Tabl. 1). The sprung of triticale in 2016 occured 27 days after sowing and in 2017 after 10 days. The duration of this growth stage period depended on the amount of the precipitation, but was limited especially by the average daily air temperature.Although in 2016 the sum of the active temperatures and the amount of rainfall were higher than in 2017, the average daily temperature (6.6 ^{0}C) was lower, which determined the longer growth stage period in the first year.

Table 1. Characteristics of the growth stage period to tillering stage.

Years	Growth stage period	Nr. of days with active t˚C	ΣTact. ˚C	Taver. ˚C	Sum of precipitation (mm)
2016/17	sowing-sprung	27	180.6	6.6	32.9
	sprung-3th leaf	15	75.3	2.2	2.4
	3th leaf-tillering	17	153.5	9.7	124.8
2017/18	sowing-sprung	10	109.1	9.9	28.0
	sprung-3th leaf	12	193.6	9.2	17
	3th leaf-tillering	13	108.1	9.8	42.5

The growth stage period sprung-third leaf lasted between 15 and 12 days during the years of the study. In the first year the growth stage period third leaf-tillering was 17 days and in the second 12 days. Meteorological conditions were most favorable in 2017, where the average daily temperatures of the growth stage periods were stable and without variation and determined the shorter growth stage periods. From tillering to maturity were recorded a different interphase periods of the varieties (Tabl. 2).

Table 2. Characteristics of the growth stage periods tillering-maturity.

A. Kolorit

Years	Growth stage period	Nr. of days with active t˚C	ΣTact. ˚C	Taver. ˚C	Sum of precipitation (mm)
2016/17	tillering-stem elongation	13	147.3	9.7	47.9
	st.elongation-sp.emergence	26	365.6	14.2	35.7
	sp.emergence-maturity	37	746.3	23.7	15.4
2017/18	tillering-stem elongation	29	300.1	10.3	173.7
	st.elongation-sp.emergence	30	488.3	14.8	33.5
	sp.emergence-maturity	56	1115.8	20.8	162.1

B. Musala

Years	Growth stage period	Nr. of days with active t˚C	ΣTact. ˚C	Taver. ˚C	Sum of precipitation (mm)
2016/17	tillering-stem elongation	13	147.3	9.7	47.9
	st.elongation-sp.emergence	21	277.0	12.7	26.1
	sp.emergence-maturity	46	882.8	23.7	15.4
2017/18	tillering-stem elongation	34	266.6	7.8	139.8
	st.elongation-sp.emergence	35	451.8	12.9	58
	sp.emergence-maturity	53	1032.4	20.8	153.8

C. Trismart

Years	Growth stage period	Nr. of days with active t˚C	ΣTact. ˚C	Taver. ˚C	Sum of precipitation (mm)
2016/17	tillering-stem elongation	13	147.3	9.7	47.9
	st.elongation-sp.emergence	32	459.0	17.6	57.8
	sp.emergence-maturity	36	776.0	23.7	15.4
2017/18	tillering-stem elongation	48	398.8	8.3	180.5
	st.elongation-sp.emergence	31	496.3	16.0	24.9
	sp.emergence-maturity	58	1138.3	20.8	162.1

During the first year the growth stage tillering-stem elongation of all varieties was 13 days, due to the same climatic conditions and the coverness of their temperature and precipitation requierments. In 2017 the period was the shortest in the standard (29 days), where the average daily air temperature was the highest (10.3^0 C). In 2016 the growth stage period steam elongation-spike emergence was the shortest in Musala variety (21 days) and although the amount of rainfall (26.1 mm) and the average daily air temperature (12.7 ˚C) were lower compared to the other two varieties it managed to cover its temperature requirements. The average daily air temperatures (17.6 ˚C) and the amount of rainfall (57.8 mm) were the highest in Trismart variety, but the duration of the growth period was the longest (34 days). During the next year the same period was the longest in Musala variety (35 days), due to the lowest sum of the active temperatures. The growth stage period spike emergence-maturity was with duration 36- 46 days in the first year of the study. Musala entered earlier in the growth stage spike emergence, but the next stage lasted longer compared to Kolorit and Trismart varieties, due to the need of accumulating the sum of the active temperatures. In 2016 the growth stage period spike emergence- maturity was the shortest in Trismart variety

(36 days). The maturity period in the second year lasted longer compared to the first year, because of the lower average of daily temperatures. The shortest maturity period was in Musala variety (53 days) and the longest in Trismart variety (58 days).

Table 3. Dynamic of growth, g m^{-2} day^{-1}

Variety	Fertilizer level	Treatment	3th leaf-tillering		tillering – stem elongation		st.elongation – sp.emergence		spike emergence-maturity	
			2017	2018	2017	2018	2017	2018	2017	2018

		VG	16,04	18,98	24,76	31,43	62,80	82,31	35,93	34,61
Trismart	$N_6P_5K_2$	NT	17,45	14,98	13,47	15,42	46,50	66,48	20,96	27,23
		VA	15,77	17,05	20,03	21,06	54,93	71,04	19,05	25,19
		VG	16,01	16,98	21,33	20,87	54,06	75,12	22,90	28,21
	$N_{12}P_{10}K_4$	NT	14,75	15,22	22,34	25,90	46,06	68,04	26,39	30,75
		VA	15,78	17,74	24,98	28,65	52,43	71,73	23,46	32,22
		VG	15,29	17,12	26,05	26,23	52,90	70,56	24,86	36,80

The dry matter accumulation and its strenght are main physiological parameters for determining the plant productive potential as a source of biomass, which also simultaneously affect the plant reaction against the environmental factors. The dynamic of growth shows the speed of the exchange processes and the growth intensity during the different growth stages of the vegetation. During the vegetation this index changes dynamically, as the speed of the dry matter formation is determined by the specific plant activity. Until tillering the average daily growth varied from 13.09 g m^{-2} day^{-1} to 18.17 g m^{-2} day^{-1} in the first year and from 12.82 g m^{-2} day^{-1} to 23.07 g m^{-2} day^{-1} in the second year and there were no differences between the two fertilizer levels. At tillering it could be observed a positive correlation between the increased fertilizer levels and the average daily growth, as the rise for the untreated variants was in the amount of 1.39 % from Kolorit variety to 1.65 % in Trismart variety in 2016 and between 1.11 % - 1.67 % in 2017. The growth maximum was observed after stem elongation, which can be explained with the stimulating effect of the nitrogen on the synthesis processes of the cereal crops. Another reason for the increased development can be more effective utilize of the soil moisture as a result of the precipitation maximum occurance. The most intensive growth during the years of the investigation was considered by the standard, where the average daily growth of the variant treated with VA in combination with the lowest level of the fertilizer reached a maximum of 224.10 g m^{-2} day^{-1} in 2016 and 246.16 g m^{-2} day^{-1} in 2017. With the vegetation progression followed natural decrease in the dynamic of the growth.

Conclusion

During the growth stage period sowing- germination between the varieties no differences have been established and all varieties entered at the same time due to the same temperature and precipitation requierments. In conditions of insufficient rainfall the duration of germination was determined by the average daily temperature. Different interphase periods were recorded from tillering to maturity for all varieties, what serves for better understanding of the biological requierments of the studied varieties. In the study, it was shown that at tillering a positive correlation between the increased fertilizer levels and the average daily growth could be observed, as the rise for the untreated variants was in the amount of 1.39 % from Kolorit variety to 1.65 % in Trismart variety in 2016 and between 1.11 % - 1.67 % in 2017. The growth maximum was indicated after stem elongation, which can be explained with the stimulating effect of the nitrogen on the synthesis processes of the cereal crops. Hence, further investigation is required to understand better the beneficial interactive effects of PGRs and fertilization levels on the phenological development of triticale.

COMPARATIVE STUDY OF GRAIN MAIZE HYBRIDS IN THE REGION OF NORTH – EAST BULGARIA

Vanya DELIBALTOVA*

Department of Crop Science, Faculty of Agronomy, Agricultural University – Plovdiv, Bulgaria
*Corresponding author: vdelibaltova@abv.bg

Abstract

The field experiment was held in Stozher village (north-east Bulgaria) in the period 2014 - 2016. The test was performed by using blocking with four repetitions; experimental field area - 25 m^2 with winter wheat predecessor. The following hybrids were tested; PR38D89, PR37D25, PR36R10, PR37H24 and PR35F38. The total studied area was 500 m². The aim of the investigation was to establish the productivity of five maize hybrids cultivated for grain as well as recommend for growing the most suitable one under non-irrigation in region of north-east Bulgaria. All the stages of the established technology for maize growing were followed. For the purpose of determining the quantity dependence between the studied indicators, the experimental data was processed according to the Anova Method of dispersion analysis, and the differences between the variants were determined by means of the Dunkan's Multiple Range Test. The analysis of the results showed that the production possibility of hybrids maize is determined to a great degree by the meteorological conditions of the year mostly by the precipitation quantity. The highest values of elements of productivity (length of the cob, cop diameter, number of the row per cob, number of the grains per row, number of the grains per cob and mass of grains per cob) were reported with the hybrid PR35F38 and the lowest – with the PR38D89 hybrid. During the years of study the highest yield was obtained from PR35F38 – 6483 kg/ha, followed by PR36R10 – 6200 kg/ha and the lowest one – from PR38D89 hybrid – 5237 kg/ha. We recommend hybrid PR35F38 for growing being the most suitable, under non-irrigation conditions in region of north-east Bulgaria.

Keywords: *maize, hybrids, productive characteristic, yield of grain*

Introduction

The productive potential of maize is manifested when the optimal combination of a complex of factors is achieved, including the hybrid, the agroecological and climatic conditions, as well as the applied agricultural technology (Delibaltova, 2014; Dimitrova et al., 2013; Niaz et al., 2014; Popova et al., 2012; Zivkov and Matev, 2005). The hybrid type with its specific genetic potential is the most dynamic factor in production. The establishment and implementation of new maize hybrids into agricultural practice, as well as their cultivation under different soil and climatic conditions has been the subject of a number of research experiments (Chen et al., 2013; Dong et acal. l.,2016; Kandil, 2013; Popova et al., 2015; Sevov, et al., 2014; Sevov, et al., 2015; Yankov et al., 2014). Choosing the most suitable hybrids for the given region according to the conditions and the cultivation technology, leads to obtaining the targeted results and ensures stable yields (Delibaltova, 2009; Kirchev, 2016; Liu, et al., 2012) . According to Tsankova et al. (2006) the agro-climatic conditions of the region of North-Eastern Bulgaria are suitable for cultivation of FAO 400 – 600 maize hybrids. 'Pioneer' Company offers Bulgarian farmers high quality maize hybrids, which have been adapted to different conditions and included in the Bulgarian varietal list. That was the reason to focus our efforts on studying the highly productive hybrids of 'Pioneer' Company in years with different climatic conditions in the region of North-Eastern Bulgaria.

The aim of the investigation was to establish the productivity of five maize hybrids cultivated for grain as well as recommend for growing the most suitable one under non-irrigation in region of north-east Bulgaria.

Material and Methods

The field experiment was held in Stozher village (north-east Bulgaria) in the period 2014 - 2016. The test was performed by using blocking with four repetitions; experimental field area - 25 m^2 with winter wheat predecessor. The following hybrids were tested; PR38D89, PR37D25, PR36R10, PR37H24 and PR35F38. The total studied area was 500 m². The experiment was performed on leached chernozem soil type.

Ploughing-in of the stubble was performed in August after the forecrop was gathered, and deep ploughing at 25 - 28 cm was performed in October; pre-sowing cultivation with harrowing was performed twice in March and April. Fertilization was performed in autumn before deep ploughing, with 8 kg active substance phosphorus and 10 kg active substance potassium and before sowing with 18 kg active substance nitrogen. The sowing was performed in the second decade of April as the seeds were pre-processed against diseases and pests (by Vitavax – 250 ml / 100 kg seeds and by Diafuran 2.5 l / 100 kg seeds respectively). Herbicide Gardian3000 ml/ ha was applied before sowing and Merlin duo – 1500 ml/ha was applied during vegetation of maize for weed control. All the stages of the established technology for maize growing under non-irrigation conditions were followed. Harvesting was done at full maturity. The grain yield is determined with standard grain moisture of 13%.

The indices length of the cob (cm), cob diameter (mm), number of the row per cob, number of the grains per row, number of the grains per cob, mass of the grains per cob (g) and grain yield (kg/ha) were determined.

For the purpose of determining the quantity dependence between the studied indicators, the experimental data were processed according to the Anova Method of dispersion analysis, and the differences between the variants were determined by means of the Dunkan's Multiple Range Test (Dunkan, 1995).

The major climatic factors determining the growth, development and productivity of maize are temperature and rainfall, their combination and distribution throughout the vegetation season.

The years of the study (2014-2016) differed significantly in the amount and distribution of rainfall during vegetation (Fig. 1). Its amount in the first experimental year was 317 mm, i.e. 63.1 mm higher than the amount measured for a long period of time. During the critical stages of plant growth and development, the crop was well supplied with moisture and that determined 2014 as a favourable year for maize production. The amount of rainfall between April and August 2016 was 256 mm or 61 mm less than the first year of the study, but those values were very close to the values reported for a long period of time, which determined the third year of the experiment as good for the studied hybrids. The least amount of vegetation rainfall was reported in 2015 – only 125 mm, versus 253.9 mm measured for a long period of time. The insufficient amount of moisture in June and July (3 and 4 mm, respectively) when maize was in the critical stages of development, determined the second experimental year as dry and unfavourable for the crop. Comparing the values of the average monthly temperatures during the years of the study showed that they were very close in all the three years and they were higher than those measured for a long period of time (Fig. 2). Just those temperature values in combination with the reported vegetation rainfall had an effect on the growth and development of the plants.

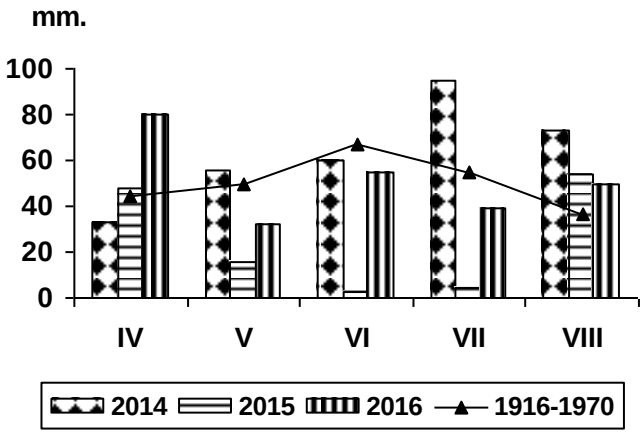

Fig.1. Rainfall, mm

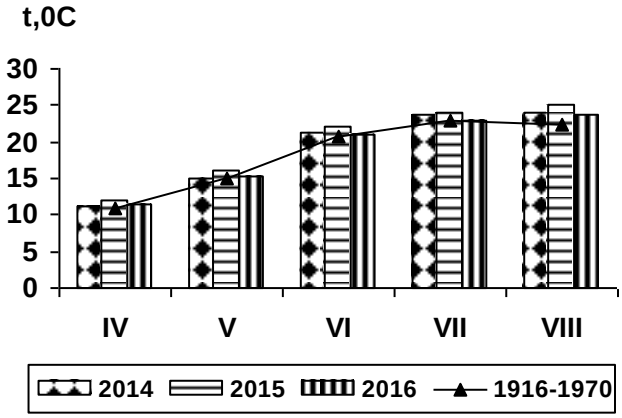

Fig.2. Average monthly air temperature, ^{0}C

The most favourable for maize growth and development was the first experimental year (2014), followed by the third (2016), and unfavourable was the second year (2015), of the experiment, having an effect on the productive potential of the studied maize hybrids.

Results and Discussion

The established structural elements of the yield are presented in Table 1. Data showed that those characteristics change under the influence of the meteorological factors during the years of the study. The highest values of the major structural elements of the yield were recorded during 2014 economic year, followed by those reported in 2016 and the lowest were registered in 2015. Compared to the other studied hybrids, PR35F38 was characterized by longer cobs, a larger diameter of the cob, a larger number of rows and grains per cob, as well as by a higher grain weight per cob.

In the first experimental year, the cob length ranged from 19.5 cm in hybrid PR38D89 to 21.4 cm in PR35F38, whereas in 2015 the values of that characteristic were significantly lower (by 38% on average) and they were from 14.0 to 15.6 cm. In 2016 the cob length ranged from 17.2 to 19.1 cm.

On average for the period of the study, the cob length of hybrid PR35F38 was 18.7 cm and exceeded the hybrids PR36R10 and PR37D25 by 6.2%, the hybrid PR37H24 – by 8.7% and PR38D89 – by 10.6%.

Data about the cob diameter of the studied hybrids showed that during the first experimental year the values ranged from 42 mm in PR38D89 to 55 mm in PR35F38, while in 2015, which was unfavourable for maize production, the values were 7 to 11 mm smaller.

On average for the period 2014-2016, the cob diameter in the studied hybrids ranged from 39.0 to 50.0 mm. The lowest values of that characteristic were reported in hybrid PR38D89 and the highest – in the hybrid PR35F38. Hybrids PR37D25 and PR36R10 had a cob diameter of 43.3 and 46.3 mm, respectively. Hybrid PR35F38 exceeded in cob diameter the hybrids PR38D89, PR37H24, PR37D25 and PR36R10 by 28.2%, 20.0%, 15.5% and 7.8% respectively.

The number of rows per cob is a genetically determined characteristic (Valkova, 2007). The reported values varying in number from 14.0 to 16.0, from 12.6 to 14, and from 13.4 to 14.8 in 2014, 2015 and 2016, respectively, showed that this characteristic was less affected by the conditions during the years of the study than the cob length. However, the number of rows per cob in all the studied hybrids in the first year was 11.5% and 5.5% higher on average than in the second and in the third year.

Hybrid PR35F38 had from 2.8% to 14.3% larger number of rows per cob in the separate years, compared to the others hybrids included in the study. The lowest values of that characteristic were recorded in hybrid PR38D89 – 13.3 rows and on the average for the years of the study, the hybrid had 12% less rows per cob compared to PR35F38 and 6.7% less number of rows per cob on average, compared to hybrids PR37H24, PR37D25 and PR36R10. During 2014, which was favourable for plant growth and development, the highest values of the number of grains in a row were reported. Their number ranged from 34.0 in hybrid PR38D89 to 42.0 in PR35F38. Hybrid PR36R10 surpassed the hybrids PR37D25 and PR37H24 by 4.5 and 5.7%, respectively, and hybrid PR38D89 – by 9.4%, but fell behind PR35F38 by 11.9%.

Table1. Structural elements of the yield

Indices	Years of study	Hybrids				
		PR38D89	PR37D25	PR37H24	PR36R10	PR35F38
Length of the cob, cm	2014	19.5	20.1	19.7	20.2	21.4
	2015	14.0	14.3	14.6	14.7	15.6
	2016	17.2	18.4	17.4	18.0	19.1
	Average	16.9	17.6	17.2	17.6	18.7
Cob diameter, mm	2014	42.0	46.0	44.0	52.0	55.0
	2015	35.0	41.0	38.0	41.0	44.0
	2016	40.0	43.0	43.0	46.0	51.0
	Average	39.0	43.3	41.7	46.3	50.0
Number of the row per cob	2014	14.0	15.0	14.3	15.2	16.0
	2015	12.6	13.2	13.6	13.4	14.0
	2016	13.4	14.0	14.0	14.4	14.8
	Average	13.3	14.1	14.0	14.3	14.9
Number of the grains per row	2014	34.0	35.6	35.2	37.2	42.0
	2015	27.5	29.0	29.5	28.4	31.0
	2016	30.0	34.0	35.0	36.0	38.0
	Average	30.5	32.9	33.2	33.9	37.0
Number of the grains per cob	2014	415.6	530.2	505.1	524.0	583.2
	2015	235.4	278.0	265.0	260.8	311.0
	2016	392.8	470.1	420.0	486.5	507.0
	Average	374.9	426.1	396.7	429.8	467.1
Mass of the grains per cob, g	2014	157.2	161.0	160.7	167.3	174.8
	2015	84.3	97.0	96.2	96.0	97.8
	2016	120.7	140.0	132.3	149.5	160.0
	Average	120.7	132.7	129.7	137.6	144.2

In the dry and unfavourable for maize 2015, a smaller number of grains in a row was established compared to the previous one. In the studied hybrids that characteristic was from 27.5 to 31.0, the differences between the hybrids ranging from 0.9 to 3.5.

In the third year of the study, the maize hybrids yielded from 30.0 to 38.0 grains per row, exceeding those produced in 2015 by 9.1% to 22.6%, but falling behind those produced in 2014 by 10.5% to 13.3%.

The largest number of grains in a row, on average for the study period, was obtained in hybrid PR35F38 – 37.0 grains, followed by PR36R10 – 33.9, PR37H24 – 33.2 and PR37D25 – 32.9. The lowest value was recorded for hybrid PR38D89 – 30.5 grains.

The number of grains per cobs in the studied hybrids varied throughout the years of the experiment and ranged from 415.6 to 583.2 in 2014, from 235.4 to 311.0 in 2015 and from 322.8 to 507.0 in 2016, respectively. In the first year of the study, hybrid PR35F38 produced 167.6, 78.1, 59.2 and 53 more grains per cob, in the second one – 75.6, 46, 50.2 and 33 more grains and in the third one – 114.2, 87, 20.5 and 36.5 more grains, compared to hybrids PR38D89, PR37H24, PR36R10 and PR37D25, respectively.

On average for the period 2014-2016, hybrid PR35F38 yielded 467.1 grains per cob and exceeded the other studied hybrids by 15.2% on average.

The grain weight per cob is one of the most important structural elements of the yield and to a certain extent it determines the productivity of maize hybrids. The values of that characteristic in all the studied hybrids were the highest in 2014, ranging from 157.2 to 174.8 g, while in 2015 and 2016 the values were from 72.9 to 77 g lower and from14.8 to 36.5 g lower, respectively.

The highest grain weight per cob (on average for the experimental period) was established in hybrid PR35F38 – 144.2 g, surpassing hybrid PR36R10 by 4.8%, hybrid PR37D25 by 8.7%, hybrid PR37H24 by 11.2% and hybrid PR38D89 by 19.5%, respectively.

The results obtained for the grain yield of the studied maize hybrids showed that both the productivity elements and the values of that characteristic varied depending on the meteorological conditions during the years of the experiment (Table 2). The amount of rainfall during vegetation, its good distribution and the combination with the average monthly temperatures favoured the higher yields obtained in the first year compared to the second and the third year of the study.

In 2014, the highest statistically significant yield was obtained from hybrid PR35F38 (9100 kg/ha), followed by PR36R10 (8800 kg/ha), PR37D25 (8520 kg/ha) and the lowest – from hybrid PR38D89 (7000 kg/ha).

The insufficient rainfall during the vegetation season in 2015, especially during the stages of maize tasseling and silking, was the reason for the low grain yields. They varied from 2010 to 2650 kg/ha for the studied hybrids. In that year, hybrid PR36R10 surpassed in yield hybrids PR37D25 and PR37H24 by 9.1 and 14.3%, respectively, but fall behind hybrid PR35F38 by 10.4%, the values being significant.

Table 2. Grain yield, kg/ha

Hybrids	Years of study			Average for the period, kg/ha
	2014 kg/ha	2015 kg/ha	2016 kg/ha	
PR38D89	7000 [a]	2010 [a]	6700 [a]	5237
PR37D25	8520 [c]	2200 [c]	7250 [c]	5990
PR36R10	8800 [d]	2400 [d]	7400 [d]	6200
PR37H24	7600 [b]	2100 [b]	7050 [b]	5583
PR35F38	9100 [e]	2650 [e]	7700 [e]	6483
LSD $_{5\%}$	*225*	*86*	*143*	

It was statistically proven that the average yield obtained from hybrid PR35F38 was 27.2% higher compared to the other studied hybrids.

In the third year of the experiment (2016), the grain yield ranged from 6700 to 7700 kg/ha, i.e. it was significantly higher (from 4690 to 5050 kg/ha) compared to the previous 2015. The highest yield was obtained from hybrid PR35F38 and it exceeded PR36R10, PR37D25 and PR37H24 by 300, 450 and 650 kg/ha, respectively, the differences being statistically significant. The lowest yield was obtained from hybrid PR38D89, the values being 14.9% less than the yield from PR35F38, 9.2% less than PR37H24, 6.2% less than PR37D25 and 4.0% less than PR36R10, which was statistically proven.

The highest yield, on average for the period of the study, was obtained from hybrid PR35F38 (6483 kg/ha) surpassing by 4.6%, 8.2% and 16.1% hybrids PR36R10, PR37D25 and PR37H24, and the lowest yield was obtained from hybrid PR38D89 – 5237 kg/ha.

The analysis of variance of the grain yield (Table 3), showed a strong statistically proven effect of the year with its specific climatic conditions – 52%. The genetic potential of the hybrids also had a significant influence on the values of that characteristic (30%).

Table 3. Analysis of variance.

Source of Variation	*SS*	*df*	*MS*	*F*	*P-value*	*η 2*
Hybrids	7590904,05	4	1897726,0	13,62	0,000	30,0
Years	271574836,8	2	135787418,0	974,86	0,000	52,0
Interaction	3221296,67	8	402662,08	2,89	0,010	18,0
Residual	6268039,29	45	139289			

A well-proven interaction between the two factors was established (18%).

Conclusions

The productive potential of the studied maize hybrids in North-Eastern Bulgaria is largely determined by the meteorological conditions of the year and, above all, by the amount and distribution of vegetative rainfall.

The highest values of the structural elements of the yield were established in hybrid PR35F38 and the lowest – in PR38D89.

On average during the period of the study (2014-2016), the highest grain yield was obtained from PR35F38 – 6483 kg/ha, followed by PR36R10 – 6200 kg/ha and the lowest – from hybrid PR38D89 – 5237 kg/ha.

Out of the studied maize hybrids grown in the region of North-Eastern Bulgaria, it is recommended to cultivate hybrid PR35F38, as it proved to be more productive than hybrids PR36R10, PR37D25, PR37H24 and PR38D89 in climatically different years.

Abstract

Low cost and high dry matter content are the reasons why cereals play an important role in feeding ruminant animals. Nevertheless, maize forage is poor in protein content which leads to low quality and nutritive value. Regarding the high feed costs of protein supplementations, legumes can be used in livestock nutrition for their high protein content, and thus, provide cost savings. In this study, maize (*Zea mays* L.) and cowpea (*Vigna unguiculata* L.) were intercropped in different sowing densities and their monocropping equivalents were tested to determine the best intercropping system on forage yield and quality. Maize was cultivated alone (75 000 plants ha^{-1}) and intercropped with cowpea as follows: 75 000 plants ha^{-1} of maize and 37 500 plants ha^{-1} of cowpea (M_1), 75 000 plants ha^{-1} of maize and 50 000 plants ha^{-1} of cowpea (M_2) and 75 000 plants ha^{-1} of maize and 75 000 plants ha^{-1} of cowpea (M_3), in rows alternating with maize. The highest dry matter yield was produced by M_3 (20.4 t ha^{-1}), and the lowest by M_1 (17.3 t ha^{-1}). All intercropped systems had higher dry matter crude protein contents, M_1 (101 g kg^{-1}), M_2 (114 g kg^{-1}) and M_3 (125 g kg^{-1}), than the monocrop maize (79 g kg-1). Intercropping of maize with cowpea reduced neutral detergent fibre and acid detergent fibre contents, resulting in increased forage digestibility. Therefore, maize intercropping with cowpea could substantially increase forage quantity and quality, and decrease requirements for protein supplements as compared with maize monocrop.

Keywords: *Intercropping, Maize, Cowpea, Yield, Quality*

Introduction

In many regions of Europe, whole-plant maize silage is the basic feed used in the feeding of dairy cows and fattening cattle. As a cultivation system, intercropping involves the planting of two or more crop species simultaneously at the same field during a growing season (Kipkemoi et al., 2010, Costa et al., 2012, Ofori and Stern, 1987). Proper spatial arrangements, planting proportions and the maturity dates of components in maize-grain legume intercropping improve biodiversity and have many advantages over monocrop maize cropping. Although maize provides high yield in terms of dry matter, it produces forage with low protein content. However, protein is needed by livestock for growth and milk production. Protein is also needed by rumen bacteria which digest much of the feed for ruminant animals (Ghanbari-Bonjor, 2000). Therefore, it is necessary to provide livestock with protein supplements when forage quality is low. The purchase of protein supplements is expensive and results in high feed costs. Cowpea, an annual legume with a high level of protein (about twice that of maize), can be mixed with maize to improve forage protein content of diets and, thus, the costs of high quality forage production can be lowered. Intercropping has many advantages over sole cropping. It provides an efficient utilization of environmental resources, reduces risk to the cost of production, provides greater financial stability for farmers, decreases pest damages, suppresses weed growth more than monocrop, improves soil fertility through increasing nitrogen to the system and improves forage yield and quality (Francis et al., 1976; Willey, 1979). Many research studies have explored the use of intercropping for

forage production. Toniolo et al. (1987) reported significantly higher crude protein (CP) content of maize-soybean intercropping than that of monocropped maize. Javanmard et al. (2009), worked on intercropping of maize with different legumes, and showed that dry matter yield and crude protein yield of forage were increased by all intercropping compositions compared with the maize monocrop. Dahmardeh et al. (2009) concluded that intercropping of maize and cowpea resulted in more digestible dry matter and also crude protein content than maize mono-cropping. The present study was designed to determine the effect of different patterns of maize-cowpea intercropping in resource consumption on fodder yield and quality.

Material and Methods

A field experiment was carried out during the 2016 growing season at experimental fields in Bjelovar, Croatia. Meteorological data of the experimental site are presented in Table 1.

Table 1. Mean monthly air temperature and rainfall during the 2016 growing season

Weather data	Month					
	April	May	June	July	August	September
Air temperature (°C)	13.0	16.2	21.3	23.3	20.5	18.3
Rainfall (mm)	43.2	85.2	78.4	57.4	114.9	46.7

The experiment was set up as a randomized complete block design with three replicates. Maize was sown as monocrop (SM) and intercropped with cowpea as provided in Table 2. Maize hybrid seed (KWS Kolumbaris) was obtained from Seed Company "KWS". Seed of the cowpea cultivar "Dolga vigna" was obtained from Company "Sjemenarna". The treatment comprising the individual plot size was 12 m × 5 m.

Table 2. Planting densities of solo maize and maize–cowpea intercrops in various treatments

Treatment	Planting density
SM	75 000 plants ha^{-1} of maize
M_1	75 000 plants ha^{-1} of maize and 37 500 plants ha^{-1} of cowpea
M_2	75 000 plants ha^{-1} of maize and 50 000 plants ha^{-1} of cowpea
M_3	75 000 plants ha^{-1} of maize and 75 000 plants ha^{-1} of cowpea

The maize population (75 000 plants ha^{-1}) were spaced at 70 cm × 19 cm and cowpea population (37 500, 50 000 and 75 000 plants ha^{-1}) were spaced at 70 cm × 38.1 cm, 70 cm x 28.6 cm and 70 x 19 cm, respectively, in rows alternating with maize. Basic tillage was carried out by ploughing to 30 cm depth. Presowing preparation was done using a tractor-mounted rototiller. All plots were fertilized with the same amount of fertilizer before sowing, containing 200 kg of N ha^{-1}, 100 kg P_2O_5 ha^{-1} and 200 kg of K_2O ha^{-1}. Maize and cowpea were sown to a depth of approximately 5 cm by hand in April 30, 2016. Herbicides or pesticides were not applied. Hand weeding by hoe was done once when the maize was approximately 30 cm in height. The soil of the research area has an acid pH 5.0 reaction (M-KCl), poor humus (2.1%), poorly supplied with physiologically active phosphorous (8.8 mg P_2O_5/100 g soil), medium supplied with physiologically active potassium (13.4 mg K_2O/100 g soil) and richly supplied with total nitrogen amounting to 0.24%. The fresh fodders were manually harvested when the maize reached soft dough stage and cowpea at R8 stage and then chopped into 20 mm size pieces with a chaff cutter. The dry matter (DM) content was determined by drying in an oven at a temperature of 105°C to a constant mass. Crude protein (CP) was measured according to Kjeldahl (AOAC, 2000), neutral detergent fibre (NDF) and

acid detergent fibre (ADF) were measured according to the Van Soest method. Significance of the differences between the means was determined according to the least significant difference (LSD) at 0.05 probability level.

Results and Discussion

Fresh forage yields differed significantly (P<0.05) among treatments, varying between 45.8 t ha^{-1} (SM) and 61.2 t ha^{-1} (M_3). Dry matter yield of the plots showed trend similar to that for fresh forage yield (Table 3). Monocrop maize had the lowest dry matter yield (16.8 t ha^{-1}).

Table 3. Fresh forage, dry matter and crude protein yield of the studied treatments.

Treatments	Fresh forage yield t ha^{-1}	Dry matter yield t ha^{-1}	Crude protein yield t ha^{-1}
SM	45.8c	16.8c	1.33d
M_1	48.5c	17.3c	1.97c
M_2	54.0b	18.8b	2.14b
M_3	61.2a	20.4a	2.55a

Different letters in the column mean a significant difference (P < 0.05)

Cowpea can be intercropped with maize (Dahmardeh et al., 2009) and sorghum (Ahmad et al., 2007) for a higher yield and quality compared with sole cropping. One possible explanation for the higher yields of intercrops is the ability of the crops to exploit different soil layers without competing with each other. Further, higher consumption of environmental resources, agronomic practices, crop genotypes, photosynthetically active radiation and soil moisture during rainy periods by intercropping can affect the yield and potential use of the intercropping system (Ofori and Stern, 1987; Anil et al., 1998; Lithourgidis et al., 2006). Geren et al., (2008) and Htet et al., (2016) showed that legume contribution to maize in mixtures was significant and increased the total biomass yield of mixtures. In this experiment M_3 treatment had the highest CP yield of 2.55 t ha^{-1} (Table 3) of the treatments. Maize alone had the highest content dry matter (366 g kg^{-1}), while M_3 treatment had the lowest (333 g kg^{-1}). One of the main reasons for intercropping maize and cowpea is to increase silage crude protein level. As crude protein is very important in livestock feeding, silage that contains more crude protein is desirable. In this study, treatment M_3 had the highest crude protein level (125 g kg^{-1} DM), followed by M_2 (114 g kg^{-1} DM), M1 (101 g kg^{-1}), and monocrop maize (79 g kg^{-1} DM), respectively (Table 4). Results in the present study were in agreement with other studies where legumes also increased crude protein concentration when in a mixture with maize (Dawo et al., 2007; Baghdadi et al., 2016; Erdal et al., 2016; Htet et al., 2016). This could be due to higher nitrogen availability for maize in intercropping compared with the monoculture crop (Eskandari et al., 2009; Eskandari, 2012).

Table 4. Nutrient composition of maize and maize-cowpea intercropped fresh forage (g kg^{-1} DM).

Nutrient composition	Treatments			
	SM	M_1	M_2	M_3
Dry matter	366a	356b	348c	333d
Crude protein	79d	101c	114b	125a
Neutral detergent fibre	411a	391b	371c	342d
Acid detergent fibre	231a	217b	204c	192c

Different letters in the row mean significant difference (P < 0.05).

Cowpea fodder is a rich source of crude protein, giving up to 184 g kg^{-1} (Khan et al., 2010) Furthermore, protein content of cowpea forage (220 g kg^{-1}) was higher compared to some legumes such as lablab (Lablab purpureus), mucuna (Mucuna pruriens) and grass species (Sorghum sudanense), though it was the species least consumed by goats (Gwanzura et al., 2011). Dahmardeh et al. (2009) concluded that maximum crude protein percentage of forage was obtained at the milky stage and minimum crude protein was achieved at the dough stage of maize growth in maize-cowpea intercropping. According to the results obtained from this study, neutral detergent fibre contents changed between 411 g kg^{-1} DM (monocrop maize) and 342 g kg^{-1} DM (treatments M_3). The neutral detergent fibre content is important in ration formulation because it reflects the amount of forage that can be consumed by animals (Lithourgidis et al., 2006). High quality forages have low concentrations of both neutral detergent fibre and acid detergent fibre and high digestibility (Peterson et al., 1994). As lower amounts of fiber components help better digestion, it stems that soybean intercropped plots were superior to monocrop maize in terms of neutral detergent fibre and acid detergent fibre. Generally, neutral detergent fibre concentration is greater for grasses than for legumes (Dahmardeh et al., 2009). Acid detergent fibre concentrations, consisting of cellulose and lignin, are important because they determine the ability of an animal to digest the forage. As the acid detergent fibre increases, the digestibility of the forage usually decreases. The content of acid detergent fibre in treatment M_3 (192 g kg^{-1}) was lower than that of other treatments. Similar results have been reported by Dahmardeh et al. (2009) and Htet et al. (2016). Dahmardeh et al. (2009) reported that maximum ADF (31.85%) was recorded by sowing maize alone while increasing the proportion of cowpea seeds to 50% in intercropping with maize, resulted in the lowest ADF (25-89%).

Conclusion

The conclusion of the present study is that intercropping of maize with cowpea at various planting densities was shown to be an effective way to influence fresh biomass production, dry matter and crude protein content to maintain or enhance nutrient quality of fresh forage. Intercropping of maize with cowpea increased crude protein, decreased neutral detergent fibre and acid detergent fibre concentrations in fresh forage. Finally, intercropping with 75 000 plants ha^{-1} of maize and 75 000 plants ha^{-1} of cowpea was most suitable according to the nutrient composition in fresh forage.

Abstract

Cereals are high important in feeding ruminant animals for their high dry matter production and low cost. However, maize forage is poor in protein content which shows its low quality and nutritive value. Regarding to high feed costs of protein supplementations, legumes can be used in livestock nutrition for their high protein content and, thus, providing cost savings. Since legumes have low dry matter yield, acceptable forage yield and quality can obtained from intercropping cereals and legumes compared with their sole crops. In this study, maize (*Zea mays* L.) and soybean (*Glycine max* L. Merril) intercropped in different numbers of rows and their monocropping equivalents were tested to determine the best intercropping system on forage yield and quality. Maize was cultivated alone and intercropped with soybean as follows: 1 row maize to 1 row soybean (1M1S), 1 row maize to 2 rows soybean (1M2S) and 1 row maize to 3 rows soybean (1M3S). The highest dry matter yield was produced by intercropping 1M3S (19.2 t ha^{-1}) and the lowest by 1M1S (16.9 t ha^{-1}). All intercropping had higher crude protein values in dry matter 1M1S (113 g kg^{-1}), 1M2S (122 g kg^{-1}) and 1M3S (130 g kg^{-1}) than the monocrop maize (77 g kg^{-1}). Intercropping of maize with soybean reduced neutral detergent fiber and acid detergent fiber content, resulting in increased forage digestibility. The study showed that among all intercropped forages the 1M3S (1 row maize to 3 rows soybean) was preferable according to forage yield and quality than other intercropping.

Keywords: *Intercropping, Maize, Soybean, Yield, Quality*

Introduction

In many regions of Europe, whole-plant maize silage is the basic feed used in the feeding of dairy cows and fattening cattle. Although maize provides high yield in terms of dry matter, it produces forage with low protein content. Toniolo et al., (1987) observed significantly higher crude protein content of maize-soybean intercropping than that of monocropped maize. Javanmard et al., (2009) worked on intercropping of maize with different legumes. Authors pointed out that dry matter yield and crude protein yield of forage were increased by all intercropping compositions as compared with the maize monoculture. The use of maize grown for ensilaging and the seeding of soybean with maize in alternate-rows as 1 maize + 1 soybean or 1 maize + 2 soybeans highly increased the silage quality and crude protein content (Altinok et al., 2005). The intercropping yields are often higher than in sole cropping systems (Lithourgidis et al., 2007). The reasons are mainly that resources such as water, light and nutrients can be utilized more efficiently than in the respective sole cropping systems (Liu et al., 2006). The underlying principle of better resource use in intercropping is that, if crops differ in the way they utilize environmental resources when grown together, they can complement each other and make better combined use of resources than when they are grown separately (Ghanbari-Bonjor, 2000). Yield advantages occur when intercrop components compete only partly for the same plant growth resources, and inter specific competition is less than intra-specific competition (Vandermeer, 1989). Light, water and nutrients are more

completely absorbed and converted to crop biomass by intercropping. This is a result of differences in competitive ability for growth factors between intercrop components (Davis and Woolley, 1993). Efficient utilization of available growth resources is fundamental in achieving sustainable systems of agricultural production. Intercropping can conserve soil water by providing shade, reducing wind speed and increasing infiltration with mulch layers and improved soil structure (Young, 1997). Physiological and morphological differences between intercrop components affect their ability to use resources; especially cereals with legumes, have several advantages such as higher total yield, better land use efficiency (Dhima et al., 2007), yield stability of the cropping system (Lithourgidis *et al*., 2006), better utilization of light, water, and nutrients (Javanmard *et al*., 2009), improved soil conservation (Anil *et al*., 1998), soil fertility through biological nitrogen fixation, increases soil conservation through greater ground cover compared to sole cropping, and provides better lodging resistance for crops that are susceptible to lodging when grown in monoculture (Lithourgidis *et al.*, 2006) and better control of pests and weeds (Banik *et al*., 2006; Vasilakoglou *et al*., 2008). Atmospheric nitrogen fixation by legumes can reduce the competition for nitrogen in the legume-cereal intercropping system, allowing the cereals to use more soil nitrogen (Eskandari *et al*., 2009). This can affect forage quality of intercrop components because protein content is directly related to the nitrogen content of the forage (Putnam *et al*., 1986). The present study was designed to determine the effect of different patterns of maize-soybean intercropping in resource consumption on fodder yield and quality.

Materials and Methods

A field experiment was carried out during the 2016 growing season at experimental fields in Bjelovar, Croatia. Meteorological data of the experimental site are presented in Table 1.

Table 1. Mean monthly air temperature and rainfall during the 2016 growing season

Weather data	Month					
	April	May	June	July	August	September
Air temperature (°C)	13.0	16.2	21.3	23.3	20.5	18.3
Rainfall (mm)	43.2	85.2	78.4	57.4	114.9	46.7

The experimental design is set up as randomized complete block design with three replicates. Maize was seeded as monocrop (SM) and intercropped with soybean as follows: 1 row corn to 1 row soybean (1M1S), 1 row corn to 2 row soybean (1M2S) and 1 row corn to 3 row soybean (1M3S). Maize hybrid seed "KWS Kolumbaris" was obtained from Seed Company „KWS". The soybean cultivar seed known as „OAC Wallace" was obtained from Company „RWA Agro". The treatment comprising the individual plot size was 12 m × 5 m. The maize and soybean were spaced at 70 cm × 19 cm and 70 cm × 5 cm with population of 75 189 and 285 720 plants per hectare, respectively. Basic tillage was carried out by ploughing to 30 cm depth. Presowing preparation was done using a tractor-mounted rototiller. All plots were fertilized with the same amount of fertilizer before sowing, containing 200 kg of N ha^{-1}, 100 kg P_2O_5 ha^{-1} and 200 kg of K_2O ha^{-1}. Maize and soybean were sown to a depth of approximately 5 cm by hand in April 30, 2016. Herbicides or pesticides were not applied. Hand weeding by hoe was done once when the maize was approximately 30 cm in height. The soil of the research area has an acid pH 5.0 reaction (M-KCl), poor humus (2.1%), poorly supplied with physiologically active phosphorous (8.8 mg P_2O_5/100 g soil), medium supplied with physiologically active potassium (13.4 mg K_2O/100 g soil) and richly supplied with total nitrogen amounting to 0.24%. The fresh fodders were manually harvested when the maize

reached soft dough stage and soybean at R7 stage and then chopped into 20 mm size pieces with a chaff cutter. The dry matter (DM) content was determined by drying in an oven at a temperature of 105°C to a constant mass. Crude protein (CP) was measured according to Kjeldahl (AOAC, 2000), neutral detergent fibre (NDF) and acid detergent fibre (ADF) were measured according to the Van Soest method. Significance of the differences between the means was determined according to the least significant difference (LSD) at 0.05 probability level.

Results and Discussion

Fresh forage yield differences of the treatments were statistically significant (P<0.05). Fresh forage yield varied between 55.6 t ha^{-1} (monoculture maize) and 45.1 t ha^{-1} (1M1S). Erdogdu *et al.* (2013) reported that 50% corn + 100% soybean sown in alternate rows was superior to monoculture maize. Dry matter yield of the plots showed similar trend as for fresh forage yield (Table 2). Monoculture maize had the highest dry matter yield (20.3 t ha^{-1}). Monoculture maize and 1M3S treatment were not statistically different which indicated that 1M3S intercropping system was comparable to monoculture maize in terms of dry matter yield. It was reported that maize-soybean intercrops produced higher dry matter yield than either species sole (Tansı and Sağlamtimur, 1992; Geren *et al*., 2008; Eskandari, 2012; Eslamizadeh, 2015).

Table 2. Fresh forage, dry matter and crude protein yield of the studied treatments

Treatments	Fresh forage yield t ha^{-1}	Dry matter yield t ha^{-1}	Crude protein yield t ha^{-1}
SM	55.6a	20.3a	1.56d
1M1S	45.1c	16.9c	1.91c
1M2S	48.4c	18.7b	2.28b
1M3S	51.7b	19.2a	2.50a

Different letters in the column mean significant difference (P < 0.05)

One possible explanation for the higher yields of intercrops is the ability of the crops to exploit different soil layers without competing with each other. Besides, higher consumption of environmental resources, agronomic practices, crop genotypes, photosynthetically active radiation and soil moisture by intercropping raining period can affect the yield and potential use of the intercropping system (Ofori and Stern, 1987; Anil *et al*., 1998; Lithourgidis *et al*., 2006). Geren *et al*., (2008); Htet *et al*., (2016) indicated that, legume contribution to corn in mixtures was significant and increased the total biomass yield of mixtures. In this study the 1M3S treatmens had the highest crude protein yield value 2.50 t ha^{-1} (Table 2) than other treatments. Sole maize had the lowest content dry matter (345 g kg^{-1}), while 1M3S treatment had the highest value (370 g kg^{-1}). One of the main reasons of intercropping maize and soybean is to increase silage crude protein level. Since crude protein is very important in livestock feeding, silage that contains more crude protein is desirable. In this study in 2016 year, treatments 1M3S had the highest crude protein level (130 g kg^{-1} DM), followed by 1M2S (122 g kg^{-1} DM), 1M1S (113 g kg^{-1}), and monoculture maize (77 g kg^{-1} DM) (Table 3).

Table 3. Nutrient composition of maize and maize-soybean intercropped fresh forage (g kg^{-1} DM).

Nutrient composition	Treatments			
	SM	1M1S	1M2S	1M3S
Dry matter	345d	353c	362b	370a
Crude protein	77d	113c	122b	130a
Neutral detergent fibre	413ns	376ns	381ns	399ns
Acid detergent fibre	228ns	191ns	213ns	218ns

Different letters in the row mean significant difference ($P < 0.05$).

These results showed that an increased proportion of legumes in intercrops increased the crude protein contents in mixture. Results in the present study were in agreement with other studies where legumes also increased crude protein concentration when in a mixture with corn (Dawo *et al*., 2007; Dahmardeh *et al*., 2009; Baghdadi *et al*., 2016; Erdal *et al*., 2016; Htet *et al*., 2016). It could be due to higher nitrogen availability for maize in intercropping compared with the sole crop (Eskandari *et al*., 2009; Eskandari, 2012). According to the results from this study, neutral detergent fibre values changed between 413 g kg^{-1} DM (monoculture maize) and 376 g kg^{-1} DM (treatments 1M1S). The neutral detergent fiber content is important in ration formulation because it reflects the amount of forage that can be consumed by animals (Lithourgidis *et al*., 2006). High quality forages have low concentration of both neutral detergent fiber and acid detergent fiber and high digestibility (Peterson *et al*., 1994). Since lower amount of fiber components help for a better digestion, it stems that soybean intercropped plots were superior to monoculture maize in terms of neutral detergent fiber and acid detergent fiber. Generally, neutral detergent fiber concentration is greater for grasses than for legumes (Dahmardeh *et al*., 2009). The acid detergent fiber concentration values, consisting of cellulose and lignin, are important because they describe the ability of an animal to digest the forage. As the acid detergent fiber increases, the digestibility of the forage usually decreases. The value of acid detergent fiber at tretment 1M1S (191 g kg^{-1}) was lower than that at all tretments. Similar results have been reported by Dahmardeh *et al*. (2009) and Htet *et al.* (2016).

Conclusion

The conclusion of the present study is that intercropping of maize with soybean at various planting densities was shown to be an effective way to influence fresh biomass production, dry matter and crude protein content to maintain or enhance nutrient quality of fresh forage. Intercropping of maize with soybean increased crude protein, decreased neutral detergent fibre and acid detergent fibre concentrations in fresh forage. Finally, intercropping with 1M3S treatment (1 row maize to 3 rows soybean) was most suitable according to the nutrient composition in fresh forage.

Abstract

The intensification of all processes of cultivation and production of agricultural crops is a basis of the modern agriculture, which means sowing of thoroughbred seeds. Therefore, in the leading countries of the world, special attention is paid on industrial seed farming. The right management of seed farming enables complete realization of productivity of the variety and maintaining its economic and biological properties.

In the modern conditions in seed farming great attention is paid to variety replacement and variety renewal. Fast replacement of a variety provides the complete revealing of potential opportunities of new variety, which ensures the fastrefund. Renewal of the varieties provides the maintaining of high-quality traits of varieties. Proceeding from the methods of releasing of varieties, the duration of their use in production varies from one to five years. Proceeding from international experience, those countries which provide fast replacement of varieties and their renewal, receive big yield per hectare.

Nowadays, in Georgia there is no system of seed farming, the farms as usual use sub-standard seeds therefore productivity of crops is catastrophically low (wheat –1,5 t/hectare, corn - 2,5 t/hectare, potatoes - 15,0 t/hectare).

The system of seed purification of varieties is quite a long process and it takes 6-7 years. Therefore for the reduction of duration of seed purificationwe set a goal to develop the accelerated method of receiving seeds. On the basis of the researches conducted in 2013-2017 was developed the technique of the accelerated receiving of basic seeds of new and deficit varieties in 3-4 years instead of 6-7 years.

Key words: *seed farming, grade, wheat, elite, standard seeds.*

Introduction

Seed farming is a branch of agriculture, which plays an important role in receiving of a big and qualitative yield [1,2,3,4,5].In the modern conditions in seed farming great attention is paid to variety replacement and variety renewal. Fast replacement of a variety provides the complete revealing of potential opportunities of a new variety, which ensures the fast refund. At distribution of new varieties isimportant the development of separate elements of technology of their cultivation, which is differentiated depending on features of a variety. An important part of seed farming is the variety renewal, which provides maintaining of its high-quality traits [4. Proceeding from the methods of release of varieties, the duration of their use in production varies from one to five years. It is possible to sow hybrid seeds only for one year, in case of correct conducting of seed farming, hybrid varieties can be sown for 4-5 years.

The correct conducting of seed farming requires knowledge of biology of the variety [Naskidashvili Petre et al.(2013), Kevkhishvili Vladimer.(1998), Kevkhishvili Vladimer. (2001).]. Variety is a spontaneous, stable and discreet biological system. Degree of resistance of variety depends: on the consistence of the pollination way, on the level of a modification variation, on the level of cross-pollination by cultures, as in the self-pollinated varieties, as well as in the cross- pollinated ones. For example,in the cross-pollinated cultures,self-pollination decreases the productivity, also the development of plants is slowed down, many

traits get worse, ineach subsequent generation the regression is increased (5-14 generations). The reasons of deterioration in high-quality traits and features are: 1.Mechanical contamination and the pollination by the other varieties; 2. Splitting; 3. Diseases of plants. 4. Identification of mutations [Samadashvili Tsotne., Naskidashvili Petre.(2014), Popolzukhin Petre et al.(2008)];

Mechanical contamination often causes biological contamination of the variety.Biological contamination takes place in case of the absence of isolation of the sown plots. For the evaluation of mechanical contamination on seed sites is carriedout field approbation.

Seed farming ensures maintaining of high-quality traits in the process of production and provides the growth of productivity by 25-40% [1,4]. Seed farming is in close connection with the seeds maintaining,which studies questions of production of seeds and methods of definition of increase in their quality.

Nowadays, in Georgia there is no system of seed farming, the farms as usual use sub-standard seeds therefore productivity of crops is catastrophically low (wheat - 1,5 t on hectare, corn - 2,5 t/hectare, potatoes - 15,0 t/hectare ,at the same time these indices in the Europe are correspondingly : 6,5 t/hectare, 9,0 t/hectare, 60 t/hectare). The Law on seed farming, adopted in Georgia define the international names of categories of seeds:breeder seed, prebasic (superelite) seed, basic (elite) seed and certified (reproductive) seed.

Breeder seeds are the seeds received from agricultural crops and which are produced by the breeder of a variety or the person employed by him. Breeder provides maintenance of all valuable characteristics of the variety. Breederenters the variety at the StateRegister. Production of such seeds takes place at primary stage of seed farming under the name of breeding seeds. The seeds which meet requirements of the standard are called standard seeds. These seeds guarantee a high yield [SamadashviliTsotne., NaskidashviliPetre. (2014)].

World breeding achievements gave us the opportunity to carry out variety replacing once in 6-8 years. The system of seed purificationis quite a long process and it takes 5 years. Therefore, for the reduction of duration of seed purification we set a goal to develop a method of the accelerated receiving of elite seeds.

Material and Methods

For the initial material from the nurseries of selection weretakenwinter wheat varieties Bezostaya-1 and Saul-9. Both varietiesare recommendedfor the production in all wheat producing regions of Georgia. In 2013, on the Sartichalatesting station selected 3000-3000 original ears and sown in the rows on the Mukhraniagricultural experiment station. In 2014-17 studying of the generations and nurseries was carried out in four replications. Studying area of each variety made 50 sq.m.For thedevelopment of the accelerated method of seed purification four options were taken:

I option – the nursery of selection of the first year, nursery of selection of the second year, nursery of multiplication of the first year, nursery of multiplication of the second year,multiplication of the third year, superelite (5 years).

II option – the nursery of selection of the first year, nursery of selection of the second year, nursery of multiplication of the first year, nursery of multiplication of the second year, superelite (4 years).

III option – the nursery of selection of the first year, nursery of selection of the second year, nursery of multiplication of the first year, superelite(3 years).

IV option – the nursery of selection of the first year, nursery of multiplication of the first year, nursery of multiplication of the second year, superelite(3 years).

Phenological and biological studying of wheat varietieswas carried out according to the method developed by UPOV.

During the vegetative period it was studied viability of plants,the survival, thetillering, the blossoming, the maturing .The assessment of wheat variety resistance to basic diseases was carried out: to yellow and stem rust, septoria, head blight and mildew.. Economic signs of each separate varietywere studied: the plant height, productive tillers, ear length andnumber of cones on an ear, number of grains in an ear, the weight of grains of one ear, and the weight of 1000 grains. The productivity was defined in four replications on the area of2sq.m. For the establishment of varietal purity of both varietieson separate sections were studied theindexes of varietal purity, for the assessment of reliability of average sizes were defined an standard deviation, average error and variation factor. (Tables 1 and 2).

Researches were conducted on Sartichala testing territory of Gardabani district and Mukhrani testing station of Mtskheta district. Soil and climatic conditions of both territories satisfied biological requirements of a winter wheat. In the researcheswas applied the modern technology of receiving seeds of wheat (well-timed and high-quality processing of the soil, complex of agricultural measures, wide-row crops, carrying measure of fight against diseases, wreckers and weeds). In 2014-2017 the vegetative period of wheat was characterized by various climatic conditions,which was reflected in a drought and sharp fluctuations of high temperatures.

Results and Discussions

During the vegetative periodphenologicalstudy was conducted: on emergence, tillering, maturing, resistance to lodging, resistance to diseases.

In 2014-17 the economic indicators did not differ significantly and they completely revealed the characteristic traits.

During 2014-17 the height of plants varied: in Bezostaya-1 between 90.4-104.4 cm, in Saul-9 - 95.2-106.8 cm, ear length in Bezostaya-1 up to 7.6-11.1 cm, in Saul-9 –up to 10.4-11.8 cm, productive tillers of variety Bezostaya-1 within 1,7-2,5, of variety Saul-9 respectively-9 - 2,8–3,8. By number of grains in one ear of a control plant of variety Bezostaya-1 - 39.5-45,3, weight 2.2–3.0 g; in an ear of a control plant in Saul-9 respectively 42.1–52.3, weight 2.3-2.6 g; weight of 1000 grains of a variety Bezostaya-1 - 45.1-47,5 grams, of variety Saul-9 the weight of 1000 grains - 43.5-45,6 grams.

The results of studying in nurseries of selection in 2014-17 are presented in the Tables No. 1-2. Apparently in 2014 the number of off-types of variety Bezostaya-1 in the nursery of breeding of the first year was 15 plants, of variety Saul-9 - 7. In the nursery of the second year of breeding - respectively 1 and 0 plants. The received results meetthe standard requiredfor the seeds of the first category.

The number of off-types in the nursery of multiplication of the first year as a result of sowing the seeds received in the nursery of selection of the first year in variety Bezostaya-1 was 18, in variety Saul-9 - 8. By the data received in 2015, variety Bezostaya -1 did not meet the standard. Number of atypical plants in nursery of multiplication of the first year as a result of sowing the seeds received in the nursery of selectionof the second year in variety Bezostaya-1 was 6, in variety Saul-9 - 2. Bothindicators completely met the standard.

In the nursery of multiplication of the second year the number of off-types in varietyBezostaya -1 did not increase -5 plants, and invariety Saul- 9 was sharply reduced and was only 2. In nursery of multiplication of the third year the number of off-types sharply increases and in variety Bezostaya-1 reached 33, and in a variety Saul-9 - 18. In the first case the seeds were sub-standard, and in the second – on the verge.

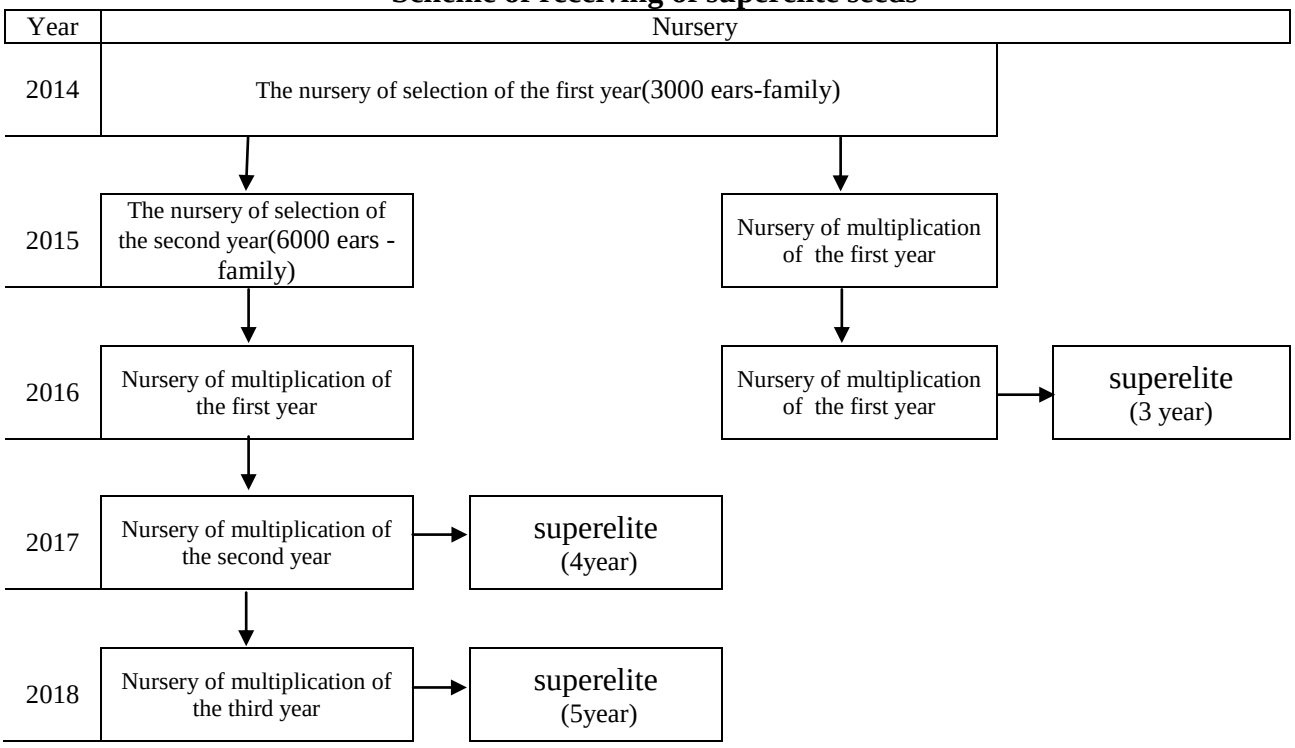
On the basis of the obtained data it is possible to present the scheme of options of the accelerated technique of receiving elite seeds as following:

Scheme of receiving of superelite seeds



On the basis of the data, obtained after using the technique of the accelerated receiving of elite seeds, confirmed with a statistical analysis, it is possible to receive the elite seeds in 3-4 years (scheme) instead of the classical scheme (7 years) provided by seed purification. The technique of the accelerated receiving of the elite seeds gives to farmers to use elite seeds and by that to provide annually a big and steady crop before the variety replacement.

Conclusion

On the basis of the experiment conducted during 2014-2017 and the analysis of the received data, we can draw the following conclusions:

For the production of elite seeds, it is possible to use the accelerated method, which gives a chance to accelerate this process for 2-3 years.

For the production of elite seeds it is possible to use the following scheme: nursery of selection of the first year, nursery of selection of the second year, nursery of multiplication of the first year, nursery of multiplication of the second year, superelite (4 years) or nursery of selection of the first year, nursery of selection of the second year, nursery of multiplication of the first year, superelite (3 years) or nursery of selection of the first year, nursery of multiplication of the first year, nursery of multiplication of the second year, superelite (3 years).

For the farmers, who own the large areas of land and need a large amount of sowing material it is better to use the following scheme: nursery of selection of the first year, nursery of selection of the second year, nursery of reproduction of the first year, superelite (4 years).

For the farmers, who own the small areas of land for producing of necessary amount of sowing material it is better to use this scheme: nursery of selection of the first year, nursery of selection of the second year, nursery of reproduction of the first year, superelite (3 years).

Four-year researches have convinced us, that the scheme for the production of elite seeds: nursery of selection of the first year, nursery of reproduction of the first year, nursery of reproduction of the second year, superelite (3 years) doesn't guarantee the receiving of standard seed material at the subsequent reproduction, therefore using of this scheme isn't recommended.

Abstract

Single-plant selection under ultra-low density (interplant distance of 100 cm), between 3 common bean (*Phaseolus vulgaris* L.) cultivars, the Greek cultivars, Iro and Pirgetos and an imported one, was performed in a honeycomb design experiment established during 2017 in the main farm of the Western Macedonia University of Applied Sciences in Florina resulting in first generation sister lines. Divergent selection of individual plants characterized as providing high (H) and low (L) yield led to 3 H and 3 L first generation genotypes, for each cultivar respectively. Salinity tolerance during germination and early seedling growth was evaluated for 18 first generation sister lines and 3 original cultivars at 0, 60, 120 and 180 mM NaCl in a randomized complete block design experiment with four replications. Germination percentage (G%), mean germination time (MGT), coefficient of velocity of germination (CVG%), time to 50% germination T_{50}, sensitivity index (SI) and fresh and dry weight of radicles and hypocotyls were measured. Salinity stress delayed germination and affected early seedling growth significantly, with the biomass of radicles plus hypocotyls decreasing with increase in salinity stress, in all genotypes tested. Significant differences were observed among first generation sister lines and the original cultivars in their response to the highest salinity stresses. Significant differences between H and L yielding lines were also shown on SI in salt stress especially within the cultivar Iro. Further research is needed to confirm the results of the present study so that any existing variation is beneficially exploited.

Keywords: *Ultra-low plant density, Salt tolerance, bean germination, Sensitivity index.*

Introduction

Common bean (*Phaseolus vulgaris* L.) is the most widely cultivated legume crop, representing near 50% of grain legumes for human consumption (McClean *et al*., 2004; Acosta-Gallegos *et al*., 2007). Common beans are essential in Mediterranean diet schemes and they are recognized as a significant source of high quality and low cost protein. Common bean is the most significant among the other pulses in Greece and in the recent years the cultivated areas are increased steadily especially in Northern and Central parts of the country (Vakali *et al.,* 2017). Modern agriculture depends by far on uniform crop varieties in order to meet a growing demand for food by the world's population, and in most cases several landraces have progressively been replaced by elite cultivars which have high agronomic performance to ensure increasing production and income, satisfying the farmers and consumer's needs (Mavromatis *et al.*, 2007). Farmers mainly use foreign certified bean varieties despite the existence of Greek varieties (Vlahostergios, 2001), which however give unstable productive results. The existence of genetic heterogeneity in Greek genotypes is offered for plant selection with methods of classical improvement and main criterion plant yield (Papadopoulos *et al.,* 2007). An intracultivar single-plant selection under ultra-low density has been extensively used to exclude plant-to-plant interference for resources as nil-competition boosts phenotypic expression and erases the masking effects induced by the negative relationship between yielding and competitive ability thus making selection of

desirable genotypes within a narrow gene pool applicable (Fasoula and Tokatlidis, 2012;Tokatlidis, 2015).

Soil salinity is an important constraint affecting agricultural productivity worldwide with over 100 million hectares worldwide affected (Qadir *et al.,* 2008). Salinity stress could be caused by poor irrigation water containing high amounts of salts, accumulation of salts in the top layer of the soil and the capillary rise of salts from underground water into the root zone due to excessive evaporation. Salinity impairs seed germination, reduces the ability of plants to utilize water and causes a reduction in growth rate as well as changes in plant metabolic processes (Munns and Tester, 2008). The probable cause of salinity toxicity is due to osmotic stress associated with lack of cell-wall extension and cell expansion leading to cessation of growth and ion toxicity interfering with nutrient imbalance within the plant thus lowering net photosynthetic rates in the affected plants (Khadri *et al.,* 2007; Cabot *et al.,* 2009). Legumes are considered a relatively salt sensitive family with the common bean germination and growth being affected at low salinity levels less than 2 dSm^{-1}. Effects of salinity during germination and early seedling growth have been reported in even lower concentrations in different bean genotypes (Bayuelo-Jimenez *et al.,* 2002; Gama *et al.,* 2007; Gutierrez *et al.,* 2009). One way reducing the deleterious effects of soil salinity on bean crop production is the development of salt-tolerant cultivars either exploiting intraspecific variability or by transferring genes from closely related wild species adapted to high salinity (Jimenez et al., 2002).

The present study was undertaken to characterize intraspecific variability for NaCl salinity tolerance in first generation sister lines of three different bean varieties during seed germination and early seedling growth. The range of variation that could exist may be utilized for identifying and developing improved genotypes which could perform better under adverse conditions.

Materials and Methods

Three common bean determinate type genotypes, two Greek cultivars Iro and Pirgetos developed by the Hellenic Industrial and Fodder Crops Institute and an imported one Northern Type were cultivated in the experimental farm of the University of Applied Sciences of W. Macedonia in Florina Greece (40°46′ N, 21°22′E, 707 m asl), in a sandy loam soil with pH 6.3, organic matter content 14.0 g kg^{-1}, N-NO_3 100 mg kg^{-1}, P (Olsen) 50.3 mg kg^{-1} and K 308 mg kg^{-1} and water holding capacity 21.8% (0 to 30 cm depth). The ultra-low density (interplant distance of 100 cm), was achieved with individual plants occupying equidistant hills in a zig-zig pattern. This density was used to preclude interplant competition and allow plant yield efficiency to be fully expressed. The trial was composed of 350 individual plants from each genotype evenly and systematically allocated according to a replicated honeycomb design (Fasoula and Tokatlidis, 2012). A total of 400 Kg/ha 0-20-0 and 200 Kg/ha 11-15-15 fertilizers were applied at planting, while additional N (50 g per plant of a 27-0-0 fertilizer) was top-dressed when plants had reached the appropriate developmental stage. Complete weed control was obtained by tilling and hand whereas irrigation was performed by a drip irrigation system. Plants were harvested individually and grain yield was measured at the physiological maturity stage and recorded at a per-plant basis.

Divergent selection of individual plants characterized as providing high (H) and low (L) yield led to 3 H and 3 L first generation genotypes, for each cultivar respectively. The 18 first generation sister lines and the 3 original cultivars were evaluated for salt tolerance during germination and early seedling growth at 0, 60, 120 and 180 mM NaCl concentration. Seeds were surface sterilized with 2% sodium hypochloride solution for 5 minutes, rinsed with sterile distilled water for several times and blotted onto sterile paper. Ten seeds from each

genotype were manually scarified by removing 1 mm of the testa with a scalpel and placed in covered, sterilized disposable Petri dishes containing filter paper moistened once with 10 ml of distilled water or NaCl solution. The Petri dishes were tightly sealed with Parafilm to prevent evaporation of water and changes in the solution concentration. A randomized complete block design with a split plot arrangement of treatments and four replications was used with NaCl treatments as main plots and the genotypes randomized within each main plot. The experiment took place in a dark automatically controlled growth chamber with a mean temperature of 25^{o}C and relative humidity 85-90%.

Seeds were considered germinated when the radicle reached 2 mm in length. Percentage germination was recorded every 24 h for 6 days. Germination percentage (G%), mean germination time (MGT), time to 50% germination T_{50} and sensitivity index (SI), ratio of median response at the three salt concentrations to the median response at the control, were calculated. At the final day fresh weights of radicles and hypocotyls were recorded and subsequently were dried at 50^{o}C for 72 h and dry weights were measured.

Comparison of means was conducted by Least Significance Difference Test (LSD) after analysis of Variance c(ANOVA), for two-factor randomized complete block design.

Results and Discussion

Final germination, germination percentage compared to the original genotypes for all first generation sister lines and mean days to 50% germination T50 are presented in Table 1 for the all NaCl treatments. Germination responses to 60 mM NaCl were not significantly different than the controls and are not shown. In all genotypes tested the germination rate was delayed in response to the highest salt concentrations and also the mean time to germination increased with the addition of NaCl. This is in agreement with other studies where moderate and high salt stress has adversely affected seed germination through osmotic effects (Bayuelo-Jimenez *et al.,* 2002; Gholami *et al.* 2009). The increase in T50 was greater at 180 mM than 120 mM with all sister lines regardless the yielding type performing better under both treatments reaching 50% germination in significantly less time than the original genotypes. No significant differences in mean germination time were shown between high yielding lines compared to the low yielding lines in all three original genotypes.

With regard to final germination percentage many first generation sister lines were relatively salt tolerant, exceeding 80% germination at 120 mM NaCl whereas two sister lines of genotype Pirgetos and one of Northern type exceeded 90% germination (Table 1). The 180 mM NaCl salt stress treatment markedly reduced final germination for all genotypes tested but all first generation sister lines performed either equally or better compared to their original genotype. Our results demonstrated genetic variation in seed germination responses to salinity among first generation sister lines and their original genotypes. Similar observations have been reported in bean (Papadopoulos *et al.,* 2007) and in lentil (Vlahostergios *et al.,* 2018) where compared to the mother populations, higher yields combined with reduced abiotic and biotic stress incidences were observed in their first-generation sister lines. The same genotypes which germinated over 90% in the 120 mM NaCl stress also reached germination percentages between 65-78% at the highest salt treatment of 180 mM which is higher than what is observed in most saline agricultural soils (75-150 mM; Gutierrez *et al.* 2009).

The sensitivity index of each genotype was estimated by the relative increase in mean germination time with the addition of NaCl compared to the control. There were differences on the stability of response to germination between original genotypes and first generation sister lines and also between high and low yielding lines especially within genotype Iro in both high salt treatments.

Table 1. Germination responses and Sensitivity Index (SI) of high (H) and low (L) yield first generation sister lines compared to the three original bean genotypes at 0, 120 and 180 mM NaCl stress.

* LSD: Least Significant Difference at P≤0.05, ns: No significant differences

Salt stress inhibited seedling growth in all genotypes tested with the magnitude of reduction being highly dependent on the salt concentration and hypocotyl growth to be more sensitive than radicle growth (data not shown). Seedling growth of high and low yielding first generation sister lines, averaged over all three original genotypes is shown in Table 2. Fresh weight of radicle, hypocotyl and total fresh seedling weight was significant different between low and high yielding lines with the low yielded genotypes to have performed better in the low and moderate salt concentrations. Similar response was shown even in the control treatment. The low yielding lines had much lower seed size with irregular seed surface which could explain faster water absorption and thereby higher seedling growth at the initial stages (Debouck, 1999). In the highest salt stress concentration there were no significant differences between the two yielding type sister lines. When dry weights were compared significant differences were shown only in hypocotyl dry weight under the low salt treatment.

In conclusion, the results of this study demonstrate that there is intracultivar variation on salt tolerance during germination and early seedling growth within first generation sister lines and these could be used to identify and develop improved genotypes which could perform better under adverse conditions. Further research is underway to confirm the results of the present study and to exploit any existing variation.

Abstract

Durum wheat is one of the most important cereal crops in Greece, both because of its nutritional value and its economic importance, and itsgood adaptation to the soil and climate conditions of the country as well. To study how the Greek durum wheat cultivars perform in the cold environment of Florina under low input conditions,eight Hellenic durum wheat varieties (cvs. Anna, Elpida, Selas, Mexikali, Athos, Papadakis, Aiantas and Thraki) were used. The complete randomized block design was applied with four replications and the experiment was established in the farm of the Western Macedonia University of Applied Sciences in Florina. The following morphological traits were measured: height and total height, the blooming, the length of spike, the number of fertile grain per spike, the length of grain as well as the germination capacity, the yield, the weight per thousand grains, the hectoliter weight, the protein content and the ashes. Differences were found between durum wheat varieties regarding germination and yield as well as the agronomic traits. No significant differences were found concerning the protein content and the ashes. More early blooming variety was the variety Thraki and the more late blooming was Athos. Regarding yield, durum wheat cultivars Anna, Mexicali and Athos were ranked first, followed by cultivar Thraki.It was concluded from the results of the present study that most of the examined cultivars performed satisfactory under low temperature and low input conditionsand could be used by wheat breeders to produce new promising varieties under similar conditions.Further research is needed to confirm the results of the present study.

Keywords: *durum wheat, yield potential, cold resistance, low input conditions.*

Introduction

Durum wheat is one of the most important cereal crops in Greece, because of its economic and nutritional value. Durum wheat has a number of traits which make it ideal for pasta-making. It also has high protein content, while its strong gluten matrix retains the starch molecules during cooking (Feillet 1984). One of the most decisive factors in the reliable production of winter cereals, including durum wheat, is resistance to extreme climatic conditions in winter.

The main factors causing winterkill (alone or in combination) are related to low temperature per se (such as extreme air or soil temperatures, below the critical temperature of a particular wheat cultivar), or prolonged periods of low sub-zero temperatures; in particular, mid-winter temperatures below -15ºC result in the rapid loss of winter hardiness (Gusta *et al*., 1997).

Handling a complex trait such as winter hardiness in a breeding program is a difficult task, due to the large number of genes involved and the numerous interactions with the environment (Saulescu and Braun 2001). A factor limiting breeding for increased frost tolerance is the variation in the occurrence of frost stress across years. But the main difficulty in breeding cold tolerant wheat is that high freezing tolerance is generally associated with lower yields and later maturity. However Friedrich *et al.,* (2013) studied the association of frost tolerance with other important traits in durum wheat reported that frost tolerance was not negatively associated with other important agronomic and quality traits.

So in order to discuss the improvement of winter hardiness, it is necessary to evaluate the relationship between yield, quality, and winter hardiness to increase the acceptance of winter durum new cultivars. The association between frost tolerance and quality is controversially discussed by breeders. Lafferty (2010) considers the combination as challenging, but not impossible and suggests a selection of quality on a level of classical quality spring durum varieties, moderate frost tolerance on bread wheat level and excellent yield performance.
The creation and use of high-yielding varieties that are resistant to abiotic stresses (such as drought, salinity, extremely low or high temperatures) and adapted to extreme environments is considered necessary (Acevedo and Fereres 1994, Lazaridou and Xynias 2017).Winters in Florina area, and especially the previous winter (2017-18) are characterized by very low temperatures so the evaluation of the existing genetic material of durum wheat (a crop adapted to dry- heat conditions) characterized by tolerance to cold is the only approach that could contribute to the problem.
The aim of the present study was to investigate the combination of frost tolerance with important agronomic and quality traits and with high grain yield in durum wheat varieties. This study was undertaken to evaluate the behavior of eight Hellenic durum wheat varieties in the cold environment of Florina under low input conditions.

Materials and methods

For the purpose of the study eight durum wheat cultivars (Anna, Elpida, Selas, Mexikali, Athos, Papadakis, Aiantas andThraki) developed at the Cereal Institute of Thessaloniki (Cereal Institute of Thessaloniki 1985) were used. The examined cultivars were sown in early November 2016 in a field at the University of Applied Sciences of W. Macedonia Farm in Florina Greece, in a sandy loam soil. Seedbed preparation included mould board plough, disc harrow and cultivator. Nitrogen and P_20_5 at 80 and 40 kg ha^{-1}, respectively, were incorporated into the soil as diammonium phosphate (20-10-0) before sowing. The crop was kept free of weeds by hand hoeing when necessary. The plots were consisted of five rows of which the three inner were harvested. The randomized complete block design (Snedecor and Cochran 1980) with four replications was used. The following morphological traits were measured: height after tillering and total height, the blooming, the length of spike, the number of fertile grain per spike, the length of grain as well as the germination capacity, the yield, the weight per thousand grains, the hectoliter weight, the protein content and the ashes. The blooming was measured as number of days from the sowing to heading. Finally an observation about thefrost tolerance of the above mentioned durum wheat cultivars was made. Data were statistically analyzed and the means were compared according to HSD test at p=0.05.

Results and Discussion

Significant differences were recorded between the examined cultivars in yield (significant differences at p = 5%, Table 1). Yield ranged from 1103.4 $kgha^{-1}$in cultivar Aiantas to 3824.1 $kgha^{-1}$in cultivar Anna (Table 1). More productive cultivars are Anna and Mexicali followed by Athos. The insufficient yield performance of cultivars Elpida and Aiantas may be due to very low germination capacity of those cultivars. Symptoms of frost stress were observed at the cultivar Athos in the leaves of three out of four replications, in plants of one replication of cultivar Mexicali, Papadakis, and Selas. All other cultivars did not show any symptoms. Nevertheless the cultivars Athos and Mexicali are among the most productive cultivars so the frost didn't cause a serious damage for the cultivars, in other words the cultivars managed to overcome this damage. Anna is the most productive variety and the most tolerant, although it is known from the literature that the traits that are associated with freezing tolerance, such as delayed spring growth or small cells, can have negative effects on yield (Saulescu and Braun

2001). The above results suggest that there must be no effect of the frost tolerance on the durum wheat cultivars performance.
Regarding the final height and the height after tillering, the differences were significant (Table 1). Total height ranged from 0.641 m in cultivar Aiantas to 0.768 m in cultivar Anna. Anna is the tallest cultivar but generally the height (after tillering and final) is low for all cultivars studied because of the extremely low temperatures of the winter. Aiantas and Thraki are the shortest varieties although Aiantas is the tallest variety after tillering.

Table 1. The germination capacity, the yield, the height after tillering and the final height of eight durum wheat cultivars

Cultivar	Germination capacity %	Yield Kg/ha	Height after tillering(m)	Final Height (m)
Anna	74.25ab	3824.1a	0.248b	0.768a
Elpida	10.25d	1561.6bc	0.244b	0.744ab
Mexikali	78.75ab	3565.5ab	0.249ab	0.702bc
Athos	78.25ab	3044.1ab	0.231b	0.711bc
Thraki	71.25ab	2573.5bc	0.236b	0.643d
Papadakis	80.00a	2256.5bc	0.235b	0.668cd
Selas	56.25bc	2250.3bc	0.231b	0.681ab
Aiantas	33.75c	1103.4bc	0.275a	0.641d

Means in columns followed by different letters, are significantly different at $p<0.05$ by Tukey's HSD test.

In all other morphological traits (the length of spike (m), the number of fertile grain/spike the length of grain) statistically significant differences were observed between the examined cultivars. (Table 2).

Table 2. The length of spike, the number of fertile grains/spike the length of grain of eight durum wheat cultivars

Cultivar	Blooming (days to heading)	length of spike (m)	number of fertile grain/spike	length of grain (m)
Anna	156	0.144a	27.90ab	0.0069a
Elpida	160	0.142a	29.50a	0.0069a
Mexikali	155	0.127b	21.22b	0.0066ab
Athos	170	0.121b	24.16ab	0.0062b
Thraki	165	0.129ab	23.22ab	0.0070a
Papadakis	167	0.135ab	25.80ab	0.0066ab
Selas	160	0.137ab	24.74ab	0.0067ab
Aiantas	159	0.144 a	25.57ab	0.0066ab

Means in columns followed by different letters, are significantly different at $p<0.05$ by Tukey's HSD test.

Khan *et al.* (2013) reported significant and positive direct effect of spike number and large indirect effects of days to heading and plant height on grain yield. In the present study it was found that the grain yield is not related to the number of kernels per spike, but to the plant height and the number of days to heading. (Tables1,2). The tallest and earliest varieties (Anna

and Mexikali) were the most productive, except cv. Athos, which is the latest variety and simultaneously among the most productive. The same was reported by Mekhlouf *et al.*,(2006) who found out that the grain yield ability, and the tolerance to low temperatures were unrelated and were represented by separate PC (principal components) components.
In all other quality traits studied, statistically significant differences were observed between the examined cultivars except protein content which is very low in all cultivars studied probably due to extreme conditions of the year (Table 3).

Table 3. The weight /thousand grains, the hectoliter weight, the protein content, and the ashes of eight durum wheat cultivars

Cultivar	hectoliter weight	weight /thousand grains	the protein content %	Ashes %
Anna	57.6	82.50	10.65a	1.65ab
Elpida	56.0	80.10	10.90a	1.53b
Mexikali	50.0	80.90	10.69a	1.63ab
Athos	45.4	85.30	10.39a	1.66a
Thraki	57.2	80.50	10.90a	1.57ab
Papadakis	48.0	83.30	11.10a	1.56ab
Selas	49.0	80.10	10.52a	1.65ab
Aiantas	48.2	78.50	11.25a	1.57ab

Means in columns followed by different letters, are significantly different at $p<0.05$ by Tukey's HSD test.

The results of this study were in agreement with Friedrich *et al.*,(2013) who found that frost tolerance was not negatively associated with other important agronomic and quality traits. In the present study the most tolerant varieties Anna, Elpida, Thraki and Aiantas had good quality features. Szucs et al. (2003), after eight years of experiments, reported that the durum wheat genotypes studied had average state of hardening and winter hardiness equal or better than those of winter *T. aestivum* varieties. From the present study it seemed that actually the durum wheat cultivars used had almost equal cold tolerance than those of *T. aestivum* varieties cultivated in the field in area near this experiment.

Conclusions

It was concluded that there are considerable differences in performance between the genotypes studied in the cold environment of Florina. From the present study it is found that the grain yield is not related to the number of kernels per spike, nor to the genotypic capacity to cold tolerance, but to the number of days to heading. The earliest varieties were the most productive. The above results suggest that there must be no effect of the frost tolerance at the productivity of durum wheat cultivars. Therefore, the breeding objective should not be to maximize winter hardiness, but to develop cultivars with the minimum winter hardiness necessary for a satisfactory performance for that region. A first estimate of these results leads to the conclusion that sufficient performance is not necessarily associated with cold resistance. However further research is needed to confirm the results of the present study.

Abstract

In Hungary, the second best-selling potted and balcony plant is geranium (*Pelargonium*) after cyclamen (*Cyclamen* sp.). Of the more than 240 types of *Pelargonium*, the most sensitive and most infected is the garden geranium (*Pelargonium hortorum*). Due to the large crossing of natural species, a large number of hybrid varieties are grown. The research was carried out in Kecskemet at the Gyenes Flower gardening. In horticulture, there are more than 80 different colors of the geranium standing, running, semi-trailer types, and the most recent F1 hybrid types and English gnawing. The geranium plants are grown in 3 greenhouses on Klasmann's peat. The research describing crop protection was carried out between 2013 and 2018. The greatest damage was caused by the Western flower thrips (*Frankliniella occidentalis*). The following insecticides were used against it: Mospillan, Admiral, Cyperkill and Lannate. The leaves and a bud damage caused destroyed the plants to a large extent. Major damage was caused by the greenhouse leaflet (*Trialeurodes vaporariorum*) and to the peat fly (*Bradysia* sp.). The larva of peat fly damaged the geranium cuttings, which could cause the geranium to develop and therefore death of the plant. Of the diseases, botrytis (*Botrytis cinerea*) was the most typical. Typical geranium rust (*Puccinia pelargonii-zonal*) did not occur in horticulture, due to the adequate prevention. Horticulture expands year by year and changes the proportions of the types of geranium according to customer needs.

Keywords: *Geranium (Pelargonium), Gyenes Flower gardening, plant protection, Frankliniella occidentalis, Botrytis cinerea*

Introduction

The geranium (*Pelargonium*) is part of the *Geraniaceae* family. Among the genus of the geranium there are annual or perennial herbaceous species, rarely woody (semi-shrubs or shrubs) (Nagy, 1975; Honfi *et al.*, 2011). The most common species is the garden geranium (*Pelargonium hortorum*) (Szántó *et al.*, 2003). To Europe, the first geranium (*Pelargonium triste*) was imported by the Dutch around 1600 from South Africa.

Today, the cultivated geranium species are of hybrid origin. The bloom depending on the variety and the season lasts 20-40 days. It is an extraneous pollinating plant. The geranium home country (South Africa), pollen mediated by the birds, while in Hungary the need for artificial pollination when the core recovery. Generally, fertility is poor. The germination strength is 71%.

The types of geranium are divided into two major groups according to the propagation method: F1 hybrids can be grown from seed heterosis and vegetative shoots propagated heterozygous varieties (Armitage and Kaczperski, 1992; Hass-Tschirschke, 1994; Burri, 2004). Heterosis breeding of varieties mainly deal with the United States. Horticulture varieties grown in Europe did not extend to plant cultivation. Vegetative propagated varieties can be grouped by growth. Small individuals grow to 20-30 cm (for example: variety of Radio, variety of Friesdorf). Middle-height individuals are 30-40 cm high (e. g. variety of Adonis, variety of Rubin). High individuals are 40 cm high (for example: variety of Hungaria) (Nagy, 1975).

The temperature requirement of the geranium moves within wide limits. Optimum temperature is 16-18 °C day and night of 12-14 °C vegetative periods. During cuttings it is 20 °C, but it can withstand 25-30 °C during the summer planting. It then blooms with the most intense water supply. The optimum temperature of the hybrid varieties is 18-24 °C (Dobay, 1998).

In addition to the optimal light conditions, the geranium develops and blooms favorably. With 25,000 lux illumination both in cultivation and outdoors, there is rapid growth, rich in flowering, rich in branching, stem does not stretch. It does not damage the 50,000 lux light when the required water content is available in the soil (Nagy, 1991).

Most of the geranium species live in their natural habitat in a dry, whimsical precipitation distribution area. Relative humidity should not exceed 70-75% in the glasshouse and foil. Particularly in the cool, dark, winter months, night and morning condensation are dangerous. If the temperature reaches the dew point, the water will precipitate on the glass, foil and drop into the plants, leading to the spread of the Botrytis (Glits and Folk, 2000). Winter irrigate geranium enough for 2-3 weeks.

The geranium species live in their original habitat on sandy humus soil. In cultivation, soil is not particularly demanding, just like other ornamental plants. The soils in the pH range of 6.3-7.2 are ideal. Nitrogen, phosphorous and potassium-rich, but excessive N content causes strong vegetative development, hindering flowering. The N deficiency causes short leaves and small leaves. Lime-rich sensitive, it induces chlorosis in plants. In the soil, the salt concentration cannot rise above 0.5% otherwise the lower leaves will be smothered by salt suffocation. Effective defense is frequent, abundant, relieving irrigation. Rooting medium consists of 70-80% peat, 20-30% clay minerals, 10-20% bark + 2.5-3 kg / m^3 carbonated lime + 0.5 kg / m^3 complex fertilizer (Nagy, 1975).

Land disinfection is inevitable because the source of soil used in propagation and cultivation is very high. In addition to soil-fungi, bacteria and weeds, we find viral infected plant parts in the soil. The soil is disinfected by steaming at high temperatures at 92-95 °C for 4-6 hours (Gerbár, 1992).

Among the most commonly used geranium pests to count the greenhouse whitefly (*Trialeurodes vaporariorum*) during the cutting propagation and growing. In summer, on the leaves of the geranium the Silver Y (*Autographa gamma*), on the geranium flower the cotton bollworm (*Helicoverpa armigera*) causes harm. Of the flower of geranium, it is regularly damaged by Western flower thrips (*Frankliniella occidentalis*) (Glits *et al.*, 1997).

Material and methods

The experiment was set up in Gyenes Flower gardening between November 2013 and March 2018 in Kecskemét (Bács-Kiskun county), Hungary. The gardener was founded in 1978, initially for gerbera (*Gerbera*) and yucca (*Yucca*) were their main crops, but switched to the geranium (*Pelargonium*) cultivation as a result of market. In horticulture, there are about than 80 variety geranium of the standing, running, semi-trailer types and English gnawing. The *Pelargonium* was different sizes and colors. These are the 6-pack, 10 to 14 cm pot made commodity.

The cuttings are taken from parent plants from excellent propagation material and rooted in a computer-controlled greenhouse with soil heating. In this way they can provide high quality cuttings for customers.

The Gyenes Flower gardening distributed by Klasmann-Deilmann GmbH, Germany Company, Klasmann TS 3 types of peat used in the cultivation of geranium. The composition of Klasmann TS 3 is a medium decomposed white filler, 0-25 mm; chemical properties: pH (H2O, v / v 1: 2.5) 6.0; Nutrient content (g / l): 1.0 and added nutrients: Nitrogen (mg N / l) 140; Phosphorus (mg P2O5 / l) 100; Potassium (mg K2O / l) 180; Magnesium (mg Mg / l)

100; Fe 13% EDTA. Physical properties: dry matter content <10%, water capacity 75-80%, air capacity 10-15%.
The following fungicides were used in protection of geranium cultivation: Amistar Top, Teldor, Signum, Topsin-M, Rovral Aquaflow.
The following insecticides were used during the experiment: Admiral, Mospilan, Kohinor, Vertimec, Warrant, Spin Tor, Cyperkill, Actara, Sumi-Alfa, Decis, Danadim, Conserve, Karate Zeon, Naturalis, Chess, Steward, Confidor, Movento, Teppeki, Laser, Dimilin, Lannate.

Results and discussion

In the Gyenes Flower gardening, we examined at plant protection of geranium with a period of nearly five years (November 2013 - March 2018). The dates of protection against pathogens and the applied fungicides are given in Table 1.

Table 1. The following fungicides were used in plant protection of geranium cultivation.

Year	Fungicide	Active ingredient
2013	Amistar Top	azoxystrobin + difenoconazole
	Teldor	fenhexamid
2014	Teldor	fenhexamid
	Amistar Top	azoxystrobin + difenoconazole
	Signum	boscalid + pyraclostrobin
2015	Teldor	fenhexamid
	Signum	boscalid + pyraclostrobin

During the examined period (2013-2018), the following pathogenic agents damaged of geranium in the Gyenes Flower gardening:
1. Fungal diseases: *Botrytis cinerea*, *Pythium debaryanum*, but rarely occurred *Alternaria porri*, *Phytophtora cryptogea*. The greatest destruction was caused by botrytis (*Botrytis cinerea*). We used the Signum and Teldor fungicide against botrytis. In addition, we increased the spacing of geraniums, and we also defended the early irrigation and frequent ventilation.
2. In order to prevent bacterial diseases, we used sterile new soil. We also protect against bacterial pathogens by continuous disinfection and ventilation of pots and greenhouses.
3. Viral disease did not occur during the examined period. The dates of protection against pests and the applied insecticides are given in Table 2.

During the experiment, the most common damages were caused by pests of greenhouse whitefly (*Trialeurodes vaporariorum*) and the Western flower thrips (*Frankliniella occidentalis*). Silwet adhesion enhancer was used to enhance the effectiveness of the insecticide. The following insecticides were used for the *F. occidentalis*: Admiral, Mospilan, Cyperkill, Vertimec, Actara, Conserve, Decis, Danadim, Spin Tor, Laser.
The following agents were used for the greenhouse whitefly: Admiral, Warrant, Sumi-Alfa, Karate Zeon, Lannate, Actara.
We used the Klasmann TS 3 growing medium of geranium cultivation, weeds did not occur, so we did not have to defend it.

Conclusions

During the experiment period (November 2013 - March 2018) botrytis caused the greatest damage to the geranium plantation. Amistar Top and Signum fungicides were the most effective against of *Botrytis cinerea*. The most common disease of geranium, rust on *Pelargonium* (*Puccinia pelargonii-zonalis*) was not typical of Gyenes Flower gardening.
Viral and bacterial diseases did not occur during the period under review.
Among the pests, the greatest damage was caused by the Western flower thrips (*Frankliniella occidentalis*) and the greenhouse whitefly (*Trialeurodes vaporariorum*).
The Mospilan, Admiral and Cyperkill insecticides were the most effective against of *Frankliniella occidentalis*. In addition to the insecticides, we also used an adhesion enhancer, Silwet. The Admiral insecticide was the most effective against of *Trialeurodes vaporariorum*.
We did not have to defend against weed because the Klasmann peat in which the geranium was raised was weeds free.

Abstract

Cut roses (*Rosa hybrida* L.) have been classified as ethylene-sensitive, but the nature of the ethylene sensitivity changes in these flowers has not been well characterized. Therefore, in this work, ethylene-insensitive cut roses consisting *etr1-1* gene were evaluated. Cut roses prepared from an isolated greenhouse at commercial stage, after transferring to the laboratory, were compared regarding the content of antioxidant enzymes by ethylene treatment (0, 0.5 and 1 $\mu l\ l^{-1}$). Evaluations were carried out in wild type and transgenic line in bud and half-open stages. The research was performed in completely randomized factorial design by four replicates. After measuring and applying the statistical differences at the $P \leq 0.05$ level via SAS software was done. The results showed that ethylene significantly increased superoxide dismutase, catalase and guaiacol peroxidase activities in bud and half-open stages in wild type and transgenic line. Maximum antioxidant enzymes activity was observed in wild type roses in bud and half-open stages treated by 1 $\mu l\ l^{-1}$ ethylene which had a significant difference in comparison with the same stage in transgenic line. According to the increasing trend of these enzymes activities in wild type and transgenic lines with higher concentrations of ethylene, it seems that, ethylene by inducing senescence oxidative damage could accelerate flower senescence. Therefore, genetic manipulation of ethylene receptor genes of ethylene-sensitive flowers as well as roses could decrease oxidatve stress during senescence and considerably improved longevity.

Keywords: *Antioxidant enzyme, Cut roses, Ethylene.*

Introduction

Roses are the most economically important ornamentals and belong to the top ten flowers in the worldwide. Cut roses account for about 21% and 31% of all cut flowers traded in China and in European auctions, respectively (Heinrichs, 2008; Meng *et al.*, 2013). Unfortunately, many consumers consider roses to have a very short vase life. Senescence is the end of the relatively short life of cut flowers that leads to the visible symptoms of various physiological characteristics (Rani and Singh, 2014). Ethylene, as a gaseous plant hormone, plays prominent role in acceleration of senescence phenomena of most plant concomitantly with increasing in endogenous ethylene production (Lei *et al.*, 2009; Rani and Singh, 2014; Rogers, 2012). In general, during the senescence process, ROS[1] content increase and accelerate senescence process by increasing cell membrane permeability. In fact, low concentrations of ROS including singlet oxygen ($^1O_2$), the alkoxy radical ($RO^{\bullet}$), hydroxyl radical ($OH^{\bullet}$), hydroperoxyl radical ($HO_2^{\bullet-}$) and the peroxy radical ($ROO^{\bullet}$) are essential as secondary messengers for cell signaling to initiate biological processes, whereas oxidative stress during senescence denotes higher ROS levels which cause damage a range of

[1] Reactive oxygen species

macromolecules such as lipids, proteins and DNA (Lei *et al*., 2009; Rani and Singh, 2014; Rogers, 2012). When ROS overproduction is triggered with progressive senescence, antioxidant system comprising of enzymatic ascorbate peroxidase, guaiacol peroxidase, glutathione reductase, catalase, superoxide dismutase and nonenzymatic components scavenge these compounds in plants (Chakrabarty *et al.*, 2009; Rani and Singh, 2014).
Plant breeding by genetic engineering technique such as transformations by *ert1-1* mutated gene resulted in plants with considerably higher ethylene tolerance (Wilkinson *et al.*, 1997). In this regard, succeeding studies were reported in *Kalanchoe* (Sanikhani *et al*., 2008), *Campanula* (Sriskandarajah *et al*., 2007; Sriskandarajah *et al*., 2010), and *Dianthus* (Gubrium *et al*., 2000), which provided a better flower longevity. ETR1 is found to be both essential and sufficient for mutations among the ethylene receptors (Chen *et al.*, 2002; Dong *et al*., 2008; Grefen *et al*., 2008).
Senescence of rose flower is still not completely understood. In order to understand petal senescence, it is important to explore the mechanisms of oxidative stress management. In this study, the levels of endogenous antioxidant enzymes during senescence of *etr1-1* transgenic rose flowers pulsed with ethylene were investigated.

Materials and methods

Plant material and ethylene treatment

Cut roses, wild type (Wt) and transgenic line (Tr), at the bud commercial were obtained directly from Iranian Research Organization for Science and Technology (Tehran). Then cut flowers were selected for the uniformity in size, shape, and freedom from malformations or damage related with harvesting and transport handling. Lower leaves were removed and flower stems were trimmed to a uniform length of 35 cm and placed in dH_2O in a growth room equipped with a controlled environment maintained at 25 ± 2 °C, 60% ± 5% relative humidity and 15 μmol m^{-2} s^{-1} light intensity for 16 h day^{-1} by cool-white fluorescent lamps.
To investigate the effects of ethylene, the samples were subjected to 0, 0.5 and 1 μl l^{-1} exogenous ethylene for 24 h in the polyethylene plastic bag. In this regard, each flower was sealed in a 7 L polyethylene plastic bag with 1 ml KOH-type for respiration CO_2 absorbance. Aliquots of pure ethylene gas were injected by syringe into the polyethylene bag. Bag ethylene concentrations were checked by gas chromatography and flowers were held in dH_2O.
Petals were collected in bud (B) and half-opened (H) stages as shown in Fig. 1. In addition, when wild type was in half-open stage, transgenic line was in bud stage at the same time. Therefore, this stage in transgenic line was called TBH (transition bud to half-open stage). Transgenic petals were collected in this stage, too (Fig. 1). In the following, immediately frozen in liquid nitrogen and then stored at -80 ºC.

Fig. 1. Three studied stages of flower development in transgenic rose: (1) bud = B, (2) transition bud to half-open stage = (TBH) and (3) half-opened = (H).

Antioxidant enzyme assay

Superoxide dismutase activity

Total superoxide dismutase (SOD) activity was determined by measuring its ability to inhibit the photochemical reduction of MTT according to the method of Giannopolitis and Ries (1977) with some modifications (Chowdhury and Cboudburi, 1985; Zhang *et al*., 1995). The 3-ml reaction mixture contained 75 μM MTT, 4 μM riboflavin, 13 mM methionine, 0.1 mM EDTA, 50 mM phosphate buffer (pH 7.4). Riboflavin was added last. The test tubes containing the mixture were placed under two fluorescent lamps at 4000 lux. The reaction was started by switching on the light and was allowed to run for 15 min. The reaction was stopped by switching off the light, and the absorbance at 560 nm was recorded. A non-irradiated reaction mixture that did not develop color served as the control, and its absorbance was subtracted from A_{560}. The reaction mixture which lacked enzyme developed maximum color as a result of maximum reduction of MTT. The reduction of MTT was inversely proportional to the enzyme activity. One unit of SOD activity was defined as the amount of enzyme required to cause 50% inhibition of the rate of MTT reduction at 560 nm.

Catalase activity

Catalase (CAT) activity was determined spectrophotometrically by measuring the rate of H_2O_2 disappearance at 240 nm, taking at 240 nm as 40 mM^{-1} cm^{-1}(Patterson *et al*., 1984). The reaction mixture contained 50 mmol/L potassium phosphate (pH 6.8), 0.1 mmol/L H_2O_2. The reaction was run at 25°C for 2 min, after adding the enzyme extract containing 20 μg of protein, and the initial linear rate of decrease in absorbance at 240 nm was used to calculate the activity.

Guaiacol peroxidase activity

Guaiacol peroxidase (G-POD) activity was measured spectrophotometrically at 25°C by following the method of Tatiana *et al*. (1999). The reaction mixture (3 ml) consisted of 25 mmol/L potassium phosphate (pH 6.8), 40 mmol/L H_2O_2, and 20 mmol/L guaiacol. The reaction was started by the addition of an enzyme extract equivalent to 50 μg protein. The formation of tetraguaiacol was measured at 470 nm (ε = 26.6 mmol/ L^{-1} cm^{-1}).

Statistical Analysis

All the data were analyzed using SAS 9.1 for Windows. The data were initially compared by one way analysis of variance (ANOVA) and difference was detected using the Duncan test. The difference between treatments was considered to be statistically significant when *P* values $\leq$ 0.05. Figures were performed using Excel and means ± standard error (S.E.) were shown. Experiments were repeated two times.

Results and discussion

SOD, CAT and G-POD activities increased during vase life and the highest activity was observed at the final stage after harvest in wild type (Fig. 2). Wild type had significant difference in all enzymes in comparison with transgenic line in the same stages (Fig. 2). It seems that ethylene exposure could be enhanced the activity of these antioxidant enzymes. Total SOD, CAT and G-POD activity enhanced in B and TBH stages in transgenic line by increasing ethylene to 0.5 μl l^{-1}. This up-trend continued in SOD activity by 1 μl l^{-1} ethylene while the activity of CAT and G-POD showed down-trend (Fig. 2b, c). It is proved that ethylene existence is necessary during opening phase (Olsen et al., 2015; Rani and Singh, 2014). SOD activity in TBH stage significantly increased in compare to other stages (Fig. 2a). TBH was considered as a transition stage from bud to half-open in transgenic line. Increasing ROS and ethylene production in TBH stage confirmed these results (data not shown). Probably, higher SOD activity in this stage could be related to ethylene sensitivity and starting the opening phase.

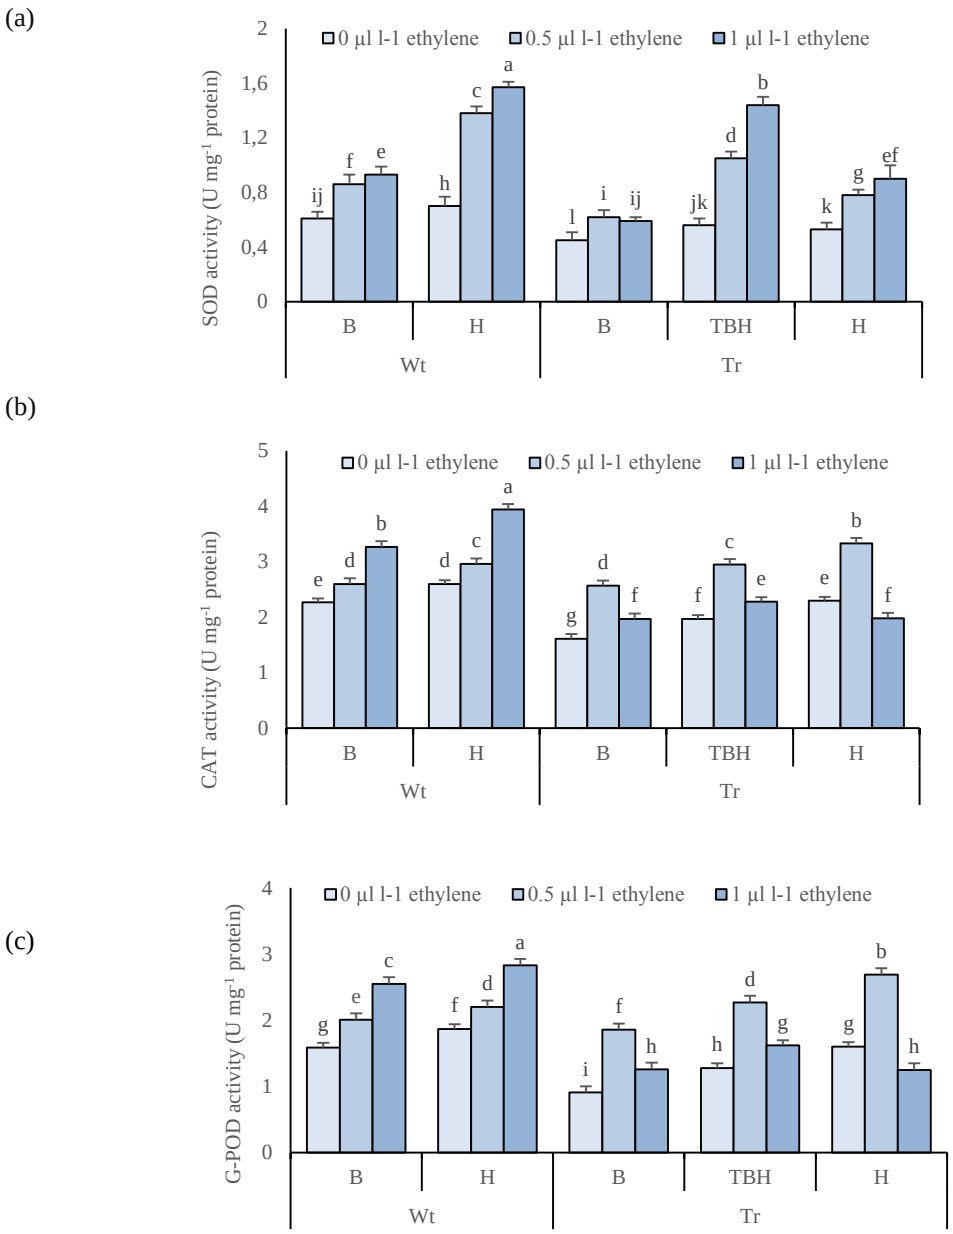

Fig 2. Changes in the level of SOD, CAT and G-POD activity in the petals of wlid type and transgenic rose line during different stages of senescence. Different letters in each bar differ significantly according to Duncan test ($P \leq 0.05$).

It has been reported, an progressive increase in antioxidant enzymes activity and increase in endogenous H_2O_2 in some plant species such as carnation, daylily and rose during senescence and application of exogenous ethylene accelerated this process (Chakrabarty *et al.*, 2009; Rani and Singh, 2014). Moreover, enhanced antioxidant enzymes activity was associated with an increase in the level of peroxides and free radicals which react with cellular constituents (Rani and Singh, 2014). In addition, antioxidant enzymes activities was found to be much higher in senescent leaves than those of in young (Rani and Singh, 2014). In this research, the main emphasis is given on enzymatic components like CAT, SOD, and G-POD which showed antioxidant behaviour with progressive senescence. Catalase is considered as an important biological factor that its major function is in the process of superoxide metabolism and plays an important role in releasing oxygen and hydrogen peroxide free

radicals and preventing creation of hydroxyl radicals (Spanou *et al*., 2012). Superoxide dismutase plays a critical role in inhibition of superoxide and guaiacol peroxidase acts as detoxification of hydrogen peroxide (Miao and St Clair, 2009). It has been reported, CAT, SOD, and G-POD play role in protection of balance of oxygen in plant tissue (Miao and St Clair, 2009; Spanou *et al.*, 2012). Accordingly, the present research indicated antioxidant enzymes activities increased during vase life by increasing exogenous ethylene concentration in wild type and transgenic line (Fig. 2). The higher activity was observed in wild type compared with transgenic line in all developmental stages (Fig. 2). The induction of SOD, CAT and G-POD activities results in decreased sensitivity to free radical-induced cellular damage (Fig. 2). The increased SOD, CAT and G-POD activity that have observed in our study could reflect a similar process of oxidative stress with the implication of these enzyme activities as part of the antioxidant response against H_2O_2. In addition, these data are consistent to previous studies that the dominant ethylene-insensitive *etr1-1* mutant has reduced affinity for ethylene and delayed flower senescence (Müller and Stummann, 2003; Olsen *et al*., 2015).

Conclusions

In conclusion, senescence could be slowed down by retarding peroxidation and high levels of antioxidant enzymes are correlated with delayed senescence. The compromise of oxidative stress in aging is a common feature to cut flowers, and this factor could be a key to designing adequate methods to prevent or delay deterioration and to improve the conservation of cut roses. It seems that transformation by *etr1* in ethylene-sensitive flowers as well as roses could be increased longevity considerably based on the disruption in perceiving ethylene by increasing antioxidant enzymes activity.

PHYSIOLOGICAL EFFECTS OF GRAFTING IN APRICOT TREES

Roberto TOMASONE*, Carla CEDROLA, Mauro PAGANO

CREA Research Centre for Engineering and Agro-Food Processing, Italy
Via della Pascolare 16, 00016 Monterotondo (RM), Italy
*Corresponding author: roberto.tomasone@crea.gov.it

Abstract

Grafting of fruit trees is a widely used agronomic practice. Depending on the purpose of its application, grafting may influence many phenological traits of the plant, such as vegetative growth, precocity of fruiting, balance between vegetative growth and fruit production, ripening time and fruit quality. In physiological terms, grafting may modify plant photosynthesis, transpiration and water use capacity. The aim of the present study was to determine the effects of different grafting techniques and of different combinations of rootstock and scion and to characterize the changes induced in the plants. In the experiment, apricot *cv.* San Castrese was studied in combination with two different clonal rootstocks: Isthara and GF677. The effects of interstock grafting were also investigated, using the Japanese apricot species *Prunus mume*. Various tests and physiological measurements were completed to quantify the effect of grafting on vegetative growth and development of the plants. All measurements were taken on leaves located in the middle of the main branches using the photosynthesis-meter Li-Cor in closed systems. Botanical assessments at the grafting point and other physiological data allowed the evaluation of the effects of grafting on plant physiology. Since water equilibrium is controlled by a complex physiological system, dependent on genetic characteristics of the species and the cultivation conditions, this study confirmed significant differences between different plants. The use of stomata conductivity and leaf temperature as indicators for determining the water balance in plants offers an effective and rapid method for characterizing the influence of water stress on plants and allows the determination of its degree of resistance to drought.

Keywords: *Rootstock, scion, disaffinity, intermediate grafting, graft union.*

Introduction

Grafting is a very ancient agronomic practice that is used for different purposes, among which the following: to make the grafted cultivars adapted to different pedo-climatic environments, to achieve a better resistance to phytosanitary adversities (pests and pathogens), to control vegetative growth and canopy habitus (Duval et al., 2012). Three main factors determine the success of the grafting: the affinity, the technique of execution and the environmental conditions. From a physiological point of view, the grafting may modify the photosynthetic efficiency, the transpiration and the hydraulic balance of the plant (Pina and Errea, 2005). During their life together, the two grafted plants influence each other reciprocally, with modifications in their vegetative and productive characteristics. The influence of the scion on the rootstock is less evident because it affects the root system, while the rootstock determines the physiological and vegetative behaviour of the cultivar, with important effects on the vigour and on growth of the scion. The most important effects induced by the rootstock concern the climatic and pedologic adaptability, the control of vigour, the quantity and quality of fruit (Di Vaio et al., 2009). The rootstock also affects the water-plant relations and the gas exchanges of the cultivar (Hernández et al., 2010).

The affinity between the rootstock and the variety is very important for the uptake of water and of the mineral elements that are necessary for an optimal growth of the grafted plant. The vascular discontinuity of the grafting joint negatively influences the continuity of

communication between scion and rootstock, being the cause of physiological disorders having consequences on plant growth. The negative effects of incompatibility become evident starting from the first phase of the grafting union and, afterwards, during the plant growth and yield, when nutrient and water requirements increase (Martinez-Ballesta et al., 2010). To overcome eventual problems related to disaffinity between rootstock and scion cultivar, the use of the intermediate graft is recommended. This technique, in addition to allowing the use of a larger number of rootstocks, also allows to restrict the growth of extremely vigorous varieties and to improve fruit quality, as a consequence of a new physiological equilibrium that is established in the plant (Tombesi et al., 2010).
The complex interactions due to the coexistence of the two plants united by grafting are strictly connected to and influenced by the cultivation environment. To study these interactions, the present experiment was set up for the establishing the capacity of assimilation and the water balance of the apricot cultivar San Castrese, grafted using both the traditional method and by means of the double inter-stem grafting.

Material and Methods

Rootstock 'GF677' is commonly used for apricot because it provides an optimal vegetative growth and an excellent fruit quality (fig. 1). Field trials were conducted at the Tree Fruit Research Centre in Rome (Italy) for the observation of the pomological traits of apricot cultivar San Castrese, grafted onto 'GF677'. Some years after planting (5-7 years) however, this particular scion/rootstock combination appeared to be weak at the point of grafting, which eventually caused the fracture of the plant at the junction point (fig. 2).

Fig. 1: Apricot cultivar San Castrese grafted onto GF677 rootstock, tree row (left) and fruit at maturity (right)

The adoption of the intermediate grafting technique was proposed as a possible solution to avoid this incompatibility. The physiological effect of a specific scion/rootstock combination, also using the Japanese apricot *Prunus mume* Sieb: et Zucc. as the interstock, was evaluated in these trials. The effect of the interstock on the plant's characteristics was determined by observing the assimilation of nutrients and the water balance throughout the productive life cycle of the plant. The Japanese apricot *Prunus mume* was chosen as the interstock, because it has a high affinity with 'GF677', the peach-almond hybrid rootstock. In addition, *P. mume* can recreate tissue continuity at the grafting point very quickly. For a further comparison, the hybrid rootstock 'Isthara' [(*Prunus cerasifera* x *P. salicina*.) x (*P. cerasifera* x *P. persica*)] was used in the tests, because it is commonly used as the rootstock in apricot orchards in Italy.

Fig. 2: The plant suffering grafting incompatibility (left),
which caused the fracture at the junction point (right)

The plant material was prepared in two phases. In June, one-year old plants of both rootstocks, 'Isthara' and 'GF677', were whip grafted with the intermediate scion *Prunus mume*, applying the technique of the green grafting during the growing season (fig. 3). A month later, after having obtained an adequate growth of the intermediate, the cultivar 'San Castrese' was also grafted as a scion over the intermediate, using the same grafting technique.

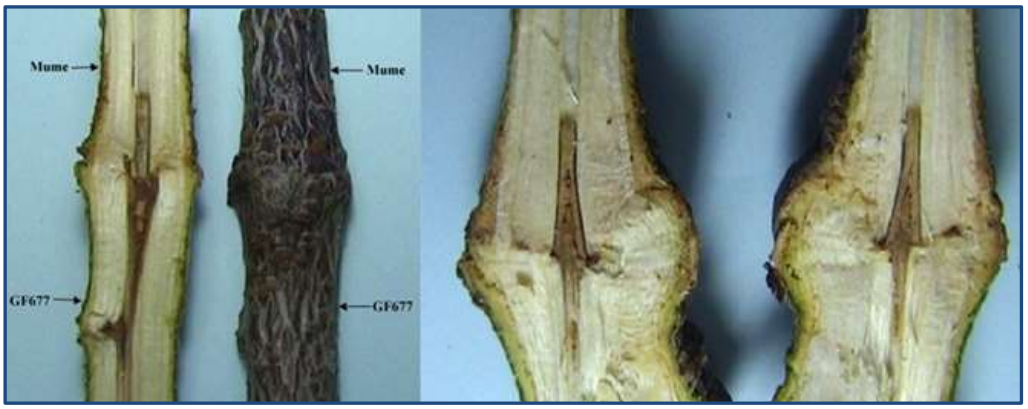

Fig. 3: The grafting of 'GF677' with *Prunus mume* interstock (left),
cross section of the well-established graft junction (right).

The planned tests were prepared applying the same method to graft the following combinations: S. Castrese/Isthara and S. Castrese/GF677. The plants were grown in pots with a controlled irrigation regime, aimed to evaluate the resistance to water drought stress. During the vegetative period, during the hours of the day characterized by the maximum sunlight, many physiological measurements were carried out, among these: photosynthesis, transpiration, conductance and stomatal resistance using Li-6400 (Licor, USA). (Fig. 4), (Horton et al., 2001). The values relating to air temperature 'Delta T' and to 'vapour-pressure deficit' (VPD) were also calculated from the data analysis.

Fig. 4: Portable gas-exchange system, Li-6400 (Licor, USA), with standard

Results and Discussion

The field trials show that both traditional grafting and, even more, intermediate grafting have an effect on the physiological parameters and on the assimilation capacity of the scion trees (Rosati et al., 1997).

The differences in the net photosynthesis values obtained for the two grafting systems (traditional and intermediate), show that the use of *Prunus mume* as an intermediate improves the affinity between the cv. San Castrese and the two rootstocks 'GF677' and 'Isthara', achieving a 10% and 30% increase in assimilation capacity, respectively. The same trend is also observed for transpiration, that increases by 15%-25%, and also for stomatal conductance, that is 25%-30% higher. The increase in these values is attributed to the improved connection between rootstock and scion, due to the optimal reconstruction of the tissues at the grafting point, after the insertion of the scion wood.

Regarding the plant's hydraulic balance, with reference to the ambient temperature trend, the data shows a large variability for transpiration, in particular when drought conditions occur. With the decrease of available soil water, each grafting combination shows its own threshold for resistance to water stress. With the use of the interstock, the rootstock's capacity to use the water decreases as the water content of soil in reduced. For this reason, when the orchard faces low water availability, the transpiration values are lower for both combinations, but in particular when the intermediate is grafted onto both rootstocks ('GF677' and 'Isthara'). However, the rootstock 'Isthara' is capable of maintaining a higher transpiration rate, despite the hydraulic stress, thus showing a higher resistance to drought.

The difference between leaf and ambient temperatures, 'Delta T' values, obtained for the two grafting techniques (traditional and intermediate grafting) in an irrigated field, show that in the double grafted plants, the leaf temperature is lower than the ambient temperature. This is attributed to the improved affinity in the rootstock/intermediate/scion combination, that allows better transpiration, compared to the traditional grafting. Regardless the type of grafting, the leaf temperature depends on water availability and on the transpiration capacity of the plant. The vapour pressure deficit (VPD) is responsible for the movement of water vapour from inside the leaf the atmosphere. The higher the values for VPD, the higher the loss of water due to transpiration. This phenomenon also limits photosynthesis, because in water stress conditions, the gas exchanges are reduced to limit transpiration. The plants with the intermediate grafting treatment have usually lower VDP values, compared to those grafted in the traditional way. Data analysis shows the existence of the correlation between transpiration and VDP and the correlation with the Delta T, confirming the importance of the climatic conditions on the normal physiological activities of the plants in the orchard.

Conclusions

The analysis of the data collected throughout the trials clearly show the influence of the grafting technique, in particular the use of the intermediate has positive effects on the physiological activity of the plant and on the hydraulic balance. The use of the intermediate *Prunus mume* Sieb: et Zucc. has improved the affinity between the apricot cultivar 'San Castrese' and the hybrid rootstock 'GF677'. Instead, the direct grafting of 'San Castrese' onto 'GF677' has been seen to develop physiological problems as a consequence of the weakness of the graft union, after some years from planting. In addition, the double grafting treatment in an irrigated field, has positively influenced the expression of the genetic potential of the cultivars and improved their drought resistance.

Abstract

In order to meet the market demand, new seedless varieties of table grapes in Lebanon should be supplied on the market outside harvest season and their cultivation areas must be expanded to new Lebanese regions. Greenhouse cultivation could be a way to achieve this goal and nano-fertilizers would help vines to withstand the warm conditions of the Lebanese coast. In fact, there were not enough studies conducted to investigate the effect of those two agricultural practices on table grapes. The current study investigated the effect of nano-fertilizer (LITHOvit AMINO 25) application and greenhouse cultivation on phenological development-stages and production of three ARRA seedless varieties: ARRA 15, ARRA 18 and ARRA 19. Experimental treatments were: open-field (control), greenhouse, open-field/nano and greenhouse/nano. Greenhouse cultivation induced earliness in budburst and fruiting (one week), flowering (2 weeks) and harvest (3 weeks) compared to open-field despite nano-effect in all tested varieties. LITHOvit treatment did not affect budburst, fruiting, flowering and harvest dates in cultivation systems except on ARRA 18 cultivated in open-field where it caused early fruiting by 1 week. The yield was increased by LITHOvit application outdoor compared to indoor (by 19.1%, 19.1% and 6% in ARRA19, ARRA18 and ARRA 15, respectively). Finally, greenhouse cultivation seems to be an effective method to supply table grapes outside the harvest season, while LITHOvit application did not enhance vines productivity.

Keywords: *Lebanon, LITHOvit, budbreak, productivity.*

Introduction

Nano-fertilizers (NFs) are synthesized or modified form of traditional fertilizers bulk materials or extracted from different vegetative or reproductive parts of the plant by different chemical, physical, mechanical or biological methods using nanotechnology (Singh, 2017). NFs have higher surface area due to very low size of particles which are smaller than root and leaves pores (Sasson *et al.,* 2007) where highly energized LITHOvit and amine particles, sprayed finely onto the leaf surface, are taken up directly through the stomata. This led to increase yields combined with a reduced requirement for water, since with LITHOvit plants are able to keep their stomata closed longer when they are subjected to water stress (GmbH, 2018). In general, NFs are known to prevent plants from different biotic and abiotic stress where it build carbon uptake (Manjunatha *et al.*, 2016), improve chlorophyll formation and photosynthetic activity (Liu *et al.,* 2005), increase dry matter (Quasem *et al.,* 2009), penetration and uptake of nutrients (Nair *et al.,* 2010), result better crop yield and food quality and enhance soil fertility (Qureshi *et al.,* 2018). In particular, LITHOvit increases the photosynthesis rate, improves enzyme activity and brings about a general enhancement of metabolic activities which improve crop yield, quality and storage properties, accelerate growth, intensify green coloration, increase growth, vitality, pest resistance, frost and drought tolerance, enhance the supply of essential trace elements to the plants and reduce the water

requirement (GmbH, 2018). According to GmbH (2018) LITHOvit can be used on arable and pastures land as well as in greenhouses, forestry and horticulture. It is harmless to human and animals and not hazardous to water. In fact, LITHOvit can be applied at the beginning of foliation, at the time of flowering and during fruit growth. It can be also used once or several times, separately or in combination with a plant protection agent. Additionally, it can be applied using any agriculture sprayer with agitation or hand operated sprayer. It is recommended to apply it twice on vine.

From the available sources just one experiment was found as published study on the application of NFs on table grapes where Sabir *et al.* (2014) showed that nano-size Ca-based fertilizer led to remarkable enhancements in foliar development and chlorophyll concentration and improvement of vine growth, yield, berry quality attributes and leaf nutrient content of grapevines (cv. 'Narince') grown under non-favorable alkaline soil conditions. However, Davarpanah *et al.* (2017) found that the foliar application of nitrogen NFs on pomegranate increased fruit yield and other qualitative parameters.

Actually, Lebanese farmers are seeking to meet market demand for new seedless table grapes varieties with high yield and extra-seasonal products. Some previous study conducted on the effect of greenhouse cultivation on table grapes in Lebanese coast shows earliness in harvest (El Masri *et al.,* 2018). Greenhouse did not show any effect on yield and plant productivity while it was not the case in some other studies. In addition, farmers have found that nitrogen uptake is the main reason improving yield (Manjunatha *et al.,* 2016). The study objective was to investigate the effect of nitrogen Nano-fertilizers (particularly LITHOvit amino 25) on the yield and occurrence of several phenological development-stages on three seedless table grapes cultivars grown under greenhouse and open-field conditions in Lebanese coast.

Materials and methods

The experimental site was located in Byblos at 140 m above sea level. The total planted area was 0.6 hectares (ha) divided on 0.3 ha under greenhouse and 0.3 ha in open-field. Four years old seedless varieties were used in this study. The following cultivars were used: ARRA 15 (white grape), ARRA 18 (black grape) and ARRA 19 (red grape). Each cultivar occupied 0.1 ha in both cultivation systems. Vines were grafted on rootstock 1103P, trained by pergolas system and irrigated with drip irrigation. In December, vines were pruned leaving 6 buds on the main shoot (per cane). LITHOvit AMINO 25 was used as a fertilizer. LITHOvit AMINO 25 is a nutritious organic nitrogen fertilizer, a new top quality nanotechnology product created by Tribodynamic activation and micronization. It is a calcium carbonate from selected natural limestone with 25 % water-soluble free L-amino acids. It contains: 56.3 % calcium carbonate (CaCO3), 3.75% magnesium carbonate (MgCO3), 31.7% alkaline constituents (expressed as CaO-calcuim oxide), 0.2 % iron (Fe) , 0.02 % manganese (Mn) (those elements are essential in all LITHOvit product while their concentration differs in each one) and 3.1 % total nitrogen (N) (GmbH, 2018). LITHOvit amino 25 was applied on vines using two different patterns. The first application pattern started before the begging of the season (1st of September) through the 3 applications with a range of 2 weeks between each one. The second application pattern started a week after the bud break, through the 2 applications with a range of 2 weeks between each one. It was applied at a concentration of 1.5 g/L as foliar application. The four experimental treatments were: open-field (control), greenhouse, open-field/nano and greenhouse/nano. Each sub-treatment was consisted on 9 plants of each variety cultivated under the same experimental conditions. Budburst, fruiting, flowering and harvest dates were recorded by daily observation and values were expressed as number of weeks after first bud burst (week 0). At harvest yield was calculated in each treatment. Statistical analysis was done by Spss program.

Results and Discussion

Results of factorial ANOVA showed that interactive and non-interactive effects of the various factors were significant at P value ≤ 0.05 on date of fruit set. The non-interactive effect of the factor variety and the interactive effect between System of cultivation and variety had also a significant difference on date of harvest. In addition, the non-interactive effect of the factor System of cultivation had a significant difference on all parameters (Table 1).

Table 1: LSD table (parameters: yield, date of fruiting and date of harvest)

	Yield	Date of fruit set	Date of harvest
Variety	.021	.000	.000
System	.020	.000	.000
LITHOvit	.952	.001	1.000
Variety*System*LITHOvit	.855	-	-
Variety*System	.253	.000	.000
System*LITHOvit	.952	.001	1.000
Variety*LITHOvit	.954	.000	1.000

LITHovit didn't affect date of any phonological development-stage any in both cultivation systems, except fruit set of ARRA 18 cultivated in open-field, where 1 week earliness was observed after LITHOvit application. On the other hand, greenhouse cultivation caused earliness in all phonological dates despite the effect of LITHOvit. As example, regarding treated and non-treated cultivar ARRA 15, dates of budburst, flowering, fruiting and harvest were earlier 1, 2, 1 and 3 weeks respectively under greenhouse than in open-field. In the control cultivar ARRA 15 was the most delayed cultivar compared to cultivar ARRA 18 and cultivar ARRA 19 where harvest was delayed by 2 and 3 weeks respectively. However, fruit set of cultivar ARRA 19 was also delayed by 1 week compared to the two other cultivars. In fact, all dates were similar regarding all cultivars under greenhouse cultivation (Table 2).

All treatments had almost the same average yield while the lowest one was recorded in treated and non-treated plant of cultivar ARRA 19 grown under-greenhouse. It was recorded that LITHOvit application increase yield by 19.1%, 19.1% and 6% in cultivars ARRA19, ARRA18 and ARRA 15 respectively outdoor compared to indoor but this increase could not considered as significant effect (Figure 1).

Table 2: Budburst, flowering, fruiting and harvest dates recorded in all treatements.

variety	Phenological dates (week)	Open-field	Open-field /nano	Greenhouse	Greenhouse/ nano
ARRA 19	budburst	1	1	0	0
	flowering	5	5	3	3
	fruit set	7	7	6	6
	harvest	19	19	17	17
ARRA 15	budburst	1	1	0	0
	flowering	5	5	3	3
	fruit set	8	8	6	6
	harvest	20	20	17	17
ARRA 18	budburst	1	1	0	0
	flowering	5	5	3	3
	fruit set	8	7	6	6
	harvest	18	18	17	17

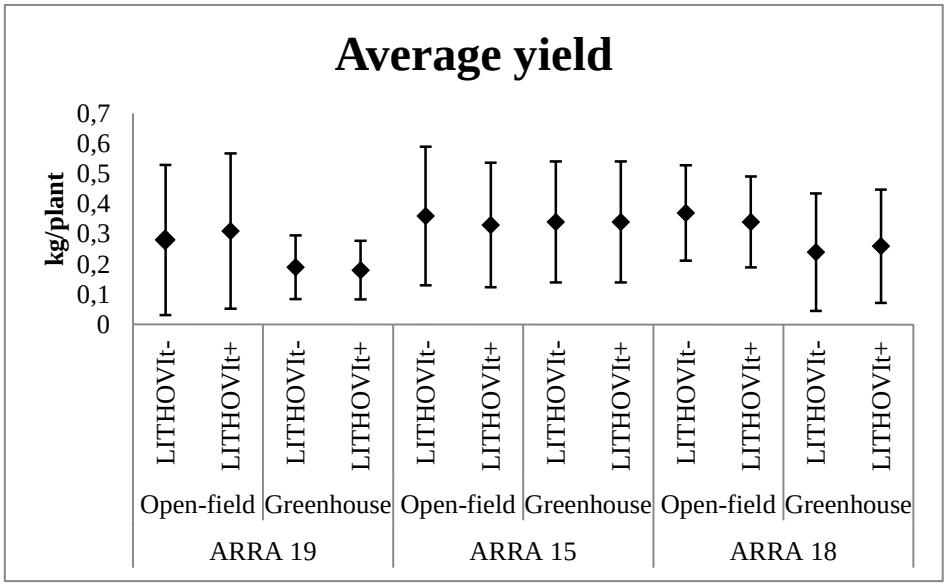

Figure 1: Average yield of plants in each treatment (kg/plant).

Early ripening under greenhouse confirmed the findings of Morettini (1974) on cv. Cardinal in Central and Southern Italy. Also, the earliness obtained by 7 to 30 days in harvest date agreed with findings of Kamiloğlu *et al.* (2011) and Novello *et al.* (2000). Moreover, the precocity in harvest has been occurring after an earlier budbreak indoor compared to outdoor. In fact, greenhouse has induced an earliness of 7 days of budbreak due to the increase of air temperature which in turn induced a faster accumulation of growing degree days (Joly, 2005; Novello and de Palma, 2008). Earlier harvest under protected cultivation was also induced by earlier maturity of fruits on vines (Ying, 2005). Ying (2005), Novello *et al.* (2000), Kamiloğlu *et al.* (2011) and Qin (2013) have observed superiority in yields under protected cultivation which contradicted our results. The effect of LITHovit amino 25 which is considered as nitrogen nano-fertilizers could be due the disturbance of vine development due to the lack of enough chilling hours in Lebanese coast. In fact, no study was published on its effect on vines to compare results.

Conclusion

Greenhouse cultivation has shortened the phenological cycle of plants reaching an earlier maturity of fruit clusters and consequently earlier yields. However, LITHovit did not show any significant results and this could be due to the lack of enough chilling hours which affect negatively budbreak and therefore flowering and fruiting capacities. Consequently, it is recommended to conduct the same study combining with addition hormone treatment which could help vine to function normally in warm winter region and compare those results with results obtained in presented study or to conduct the same study on vine planted in normal conditions in order to know the real reason behind the effect of LITHOvit on vine, since there was a lack of published paper and experiment on the effect of Nano-fertilizers on table grapes.

Abstract

Most of irrigated arable lands in Arabic countries are suffering of salinity problems either in soil or irrigation water. This problem has a strong impact on countries such as Egypt with limited natural resources of agricultural land and irrigation water, more precisely in the Northern parts of the Nile River. Therefore, this work was designed to investigate the responses of Zucchini plants (*Cucurbita pepo L.*) to salinity while applying glycine betaine (GB) to improve such responses. The experiment was carried out in an open-field in Beheira governorate, Egypt in order to study the effect of exogenous application of GB on improving salt tolerance of zucchini plants (*var. cylindrica*). Salt stress was induced by daily fertigation using saline water of an EC=6 dS/m. GB was applied through foliar spray with a concentration of 10 mM one week (first application) and four weeks (second application) after transplanting. It was found that GB application induced superiority in all tested indicators except in fruit number. Stem length, fresh weights of leaves and stems, chlorophyll content, fruit yield and weight of individual fruit were improved by 18.7%, 127%, 58%, 7%, 26% and 45% respectively. Moreover, fruits of treated plants were bigger and richer in total proteins, potassium, phosphorus and water compared to control fruits. Results revealed that GB application has helped in mitigating the detrimental effects of salinity on growth and production of zucchini plants under the current experimental conditions.

Keywords: *glycinebetaine, salt stress, zucchini, plant growth, production.*

Introduction

Plants often face the challenge of several suboptimal environmental conditions which limit plant growth and productivity. One of the major constraints to agricultural development is salt stress. Salt accumulation in soils causes high osmotic pressure reducing water potential and inhibiting plant growth (FAO, 2018). A soil is defined as saline when its electrical conductivity (EC) exceeds 4 dS/m at 25◦C (Jamil *et al.*, 2011). In Egypt, seawater intrusion in the Nile Delta is considered as a major problem facing agriculture (Mabrouk *et al.,* 2013). Although most crop plants are not able to grow in high concentrations of salts (Flowers, 2004), they have developed well-organized defense mechanisms to protect themselves from the salinity-induced damages including hormonal regulation, accumulation of compatible solutes (Bohnert and Jensen, 1996), ionic homeostasis (Hasegawa et.al., 2000) and osmoregulation.

Various compatible solutes enable plants to tolerate abiotic stress, and glycinebetaine (GB) is one of the most-studied among such solutes (Chen and Murata, 2011). Glycinebetaine (GB) is an organic osmolyte that acts as an osmoprotectant in response to salt stress in many crop species like barley and sugar beet (Mäkelä, 2004).. Glycinebetaine (N,N,N-trimethylglycine) is a quaternary ammonium (Rhodes and Hanson, 1993) resulting from the dehydrogenation of choline or N-methylation of glycine (Sakamoto and Murata, 2002) and isolated from sugar

beet molasses (Filipčev *et al.*, 2015). On the other hand, other crops are not able to synthesize GB (Sakamoto and Murata, 2000) such as zucchini. Zucchini is one of the most popular vegetable crops in Egypt where it is highly cultivated and consumed due to its beneficial nutritional properties. However, being a moderately salt-tolerant crop, its cultivated area has declined from the year 2011 due to salinity built up in Egyptian soils (Ramadan, 2014).
Positive effects of the exogenous application of glycinebetaine (GB) under salt stress conditions were reported on various crops such as rice (Harinasut *et al.*, 1996), wheat (Diaz-Zorita *et al*., 2001), tomato (Tantawy *et al.*, 2009; Razaei *et al.*, 2012) and maize (Nawaz *et al.*, 2012). However, little literature has discussed the case of zucchini. Consequently, the current work was carried out in order to evaluate the effect of exogenous GB application on vegetative growth, production and fruit composition of salt-stressed zucchini plants.

Materials and methods

The experiment was carried out in a private farm situated in Beheira governorate, Egypt. Soil analysis was performed at two different depths (0-30 cm and 30-60 cm) and soil type was determined based on Mcdonald *et al.* (1998) as sandy clay loam, with a pH of 7.4-7.7 and an electrical conductivity of 4.16-4.77 dS/m at both depth levels.
Seeds of zucchini (*Cucurbita pepo* var. *cylindrica*) were sawn in trays in a greenhouse in mid-June. In mid-July, 60 seedlings (5 to 6 leaves) were transplanted in open-field with a planting distance of 50x75 cm and were irrigated with sweet water (EC>2 dS/m).

Experimental treatments

One week after transplantation, 30 plants were treated by GB solution while the remaining plants were not (control). Second application of GB was carried out three weeks later and GB was provided with a concentration of 10 mM and an application rate of 0.5 L per plant. Salt stress was induced on all zucchini plants through saline irrigation starting at 10 DAT (days after transplantation). Saline solution was prepared by diluting well water of an initial EC=10 dS/m with sweet water to reach an EC=6 dS/m.

Data recording

At 45 DAT (before harvest), 15 plants of each treatment were selected for evaluating their stem length (from cotyledons level to the highest growing point of the stem) and leaf number. Total chlorophyll content was measured on field prior to first fruit formation using a Minolta SPAD chlorophyll-meter (SPAD unit is evaluated by 10 mg chlorophyll/100g fresh weight). This indicator was evaluated on 10 plants per treatment by selecting the most expanded leaves. Fruits were harvested twice a week after reaching a marketable stage. Plant yield was evaluated after determining the fruit number and individual fruit weight per plant. After harvest, 15 plants per treatment were randomly selected and removed from the soil to record the fresh weight of aerial parts (leaves and stems). Moreover, three representative fruits per treatment were sampled and sent to the laboratories of the National Research Center (NRC), Giza, Egypt for measuring fruit length and diameter (using a sliding caliper), moisture, protein, phosphorus and potassium contents. The various components were determined based on AOAC (2005) standard methods.

Statistical analysis

The statistical analysis was made using SPSS. The experimental design was a randomized complete block design (RCBD) with two treatments and 30 replicates (plants) per treatment. T-test was adopted for evaluating differences among both treatments.

Results and discussion

There were detrimental effects of salinity on different growth indicators investigated on zucchini plants while GB treatment induced improvements in such indicators except for leaf number (Table 1). In fact, average stem length was significantly higher in GB-treated plants

compared to control and the increment reached more than 18%. . Similar effect of GB was observed on average fresh weight of leaves (improvement by 127 %) and stems (improvement by 58 %). Moreover, total chlorophyll content was significantly enhanced by GB treatment (improvement by 7 %).

Table 1: Averages of vegetative traits in treated and non-treated zucchini plants

	S.L (cm)	L.N	Chl_T (mg/100g)	S.F.W. (g/plant)	L.F.W (g/plant)
Control	51.67[a]	23[a]	46.1a	150[a]	351.67[a]
GB-treatment	61.33[b]	25.33[a]	49.3b	238.33[b]	798.33[b]

Numbers followed by the same letters are not statistically different at *P<0.05*
S.L: stem length; L.N: leaf number, Chl_T: total chlorophyll content, S.F.W.: stem fresh weight, L.F.W.: leaves fresh weight.

Furthermore, GB application has significantly increased plant yield compared to control as shown in Table (2). GB-caused improvements in average weight of individual fruit rather than average fruit number that did not differ significantly among treatments. Average fruit length and diameter did not significantly differ among treatments although they were slightly higher in fruits of treated plants compared to control (Table 2).

Table 2: Averages of productive traits in treated and non-treated zucchini plants

	F.N.	F.W (g)	Y. (g/plant)	F.L. (cm)	F.D. (cm)
Control	5.6[a]	91.07[a]	510[a]	9.6[a]	3.8[a]
GB-treatment	4.85[b]	132.4[b]	642.41[b]	12.5[a]	4.3[a]

F.N: fruit number, F.W: fruit weight, Y: yield, F.L: fruit length, F.D: fruit diameter

Moisture, protein, potassium and phosphorus contents did not significantly differ among fruits of treated and control plants although all components were slightly higher in treated fruits (Table 3).

Table 3: Composition of zucchini fruits of treated and non-treated plants

	Moisture (%)	Protein (%)	Potassium (ppm)	Phosphorus (ppm)
Control	91.3[a]	1.36[a]	2688.07[a]	504.28[a]
GB-treatment	94.6[a]	1.45[a]	2754.73[a]	523.54[a]

Salinity-caused reductions in stem length, leaf number, chlorophyll content as well as stem and leaves fresh weights confirmed earlier findings on barley (Iyengar *et al.*, 1977), tomato (Al-Rawahy, 1989), radish (Jamil *et al.*, 2007) and squash (Mutowal *et al.*, 2013).
Salinity affects crop growth by creating osmotic imbalance in the cell (Morgan, 1984). Salts accumulated in soil and/or water may inhibit plant growth by reducing plant ability to take up water and by accumulating salts in the transpiration stream causing cell injuries in leaves and further reductions in growth (Greenway and Munns, 1980).
Amelioration in some growth indicators that was obtained following GB application was due to the role of GB in increasing water retention of cells and facilitating nutrient absorption (Ashraf and Foolad, 2007). Moreover, GB could have alleviated the negative effect of salinity

on shoot growth by inducing the production of additional vacuoles in root cells, which resulted in a greater accumulation of Na^+ in the root and a decrease in its transportation to the shoot (Rahman *et al.*, 2002). On the other hand, the non-ameliorative effect of GB on leaf number of treated plants confirmed results of Mohammed and Tarpley (2011) on rice and contradicted those of Razaei *et al.* (2012) on squash plants. In addition, GB application has improved chlorophyll content by protecting the photosynthetic machinery and stabilizing the activity of repair proteins under high concentrations of NaCl (Giri, 2011).

Figure 1: Malformed fruits by control plants (left) and well-formed fruits by GB-treated plants (right) grown under saline conditions.

Salt stress affects flowering and fruit set which reflects on number of fruits per plant, and the latter being the most influencing component of fruit yield (Rezaei *et al.*, 2012). Although Glycine betaine is an effective strategy for increasing yield of crop plants under abiotic stress (Chen and Murata, 2008), GB treatment did not enhance fruit number similar to the findings of Sajyan *et al.* (2018) on tomato. However GB treatment improved yield by 22 % due to higher fruit weight compared to control. Likewise, there was improvement in yield by GB treatments observed by Park *et al.* (2006) and Tantawy *et al.* (2009) on tomato. Moreover, fruits of control plants were malformed while those of treated plants had a better appearance (Figure 1). Fruit quality was influenced by salinity which caused inhibition of water uptake by roots and consequently lowered water transportation to the fruits (Azarmi *et al.*, 2010). The lower moisture content in control fruits was due to the high osmotic pressure induced by salinity which was responsible for the reduction of the cytoplasmic volume and the loss of cell turgor (Cicek and Cakirlar, 2002). However, treating plants with GB allowed the formation of longer and thicker fruits which might be due to better expansion of fruit cells and a better accumulation of assimilates in fruits. The nature of glycine betaine as an amino product could have enhanced the protein content of zucchini fruits confirming the finding of Al-Taweel *et al.* (2007). Glycine betaine has helped to restore the nitrogen fixation activity under salt stress and to antagonize the inhibition of protein biosynthesis, improving plant tolerance to stress (Giri, 2011). Also, saline water irrigation had a negative effect on the potassium uptake due to the competition between K^+ and Na^+ on the absorptive sites of plant roots (Ioneva, 1988). High levels of NaCl alter the export of phosphorus from root vacuoles to other plant organs (Navarro *et al.*, 2001). This caused lower potassium and phosphorus content in zucchini fruits, while on the contrary both elements were higher in fruits of treated plants as was observed in this study.

All above mentioned responses reflected on total plant fresh weight which was negatively affected by salinity and positively by GB application. Although number of leaves was not statistically different, there was a tendency to be negatively lower under salinity stress conditions. According to Alamgir and Ali (2006) salt accumulation has inhibited the formation of leaf primordial causing reduction in leaf number. This means lower leaf area which reflected negatively on a reduction in light interception hence photoassimilate

production. In addition, salt stress may cause a decline in photosynthesis due to lower stomatal conductance, depression in carbon uptake and metabolism, inhibition of photochemical capacity or a combination of these factors (Osuagwu and Udogu, 2014).

Conclusions

The result of osmotic effects of salt stress on the water and nutrient status of stressed plants ended with altering major growth parameters resulting in yield reduction. On the other hand, GB application, as an osmoprotectant, is an efficient and eco-friendly method that counteract those negative effects on zucchini plants by improving their tolerance.

Abstract

Wheat cereal grains are among the most important staple foods for the world's population. Near-infrared spectroscopy (NIRS) for determining grain chemical constituent contents has been studied over the past few decades around the world. The grain industry is in need of an automated, economical, and rapid means of determining grain quality. The aim of this work was to determine the chemical composition of wheat (*Triticum aestivum* L.) by near infrared reflectance (NIR) spectroscopy. This paper presents the chemical and amino acid composition of twelve spring wheat (n = 6) and winter wheat (n = 6) varieties grown in one location in Lithuania. Wheat grain samples of the 12 varieties were analysed for crude protein, crude fat, crude ash, crude fibre and amino acids using the FOSS NIRS™ DS2500 system according to the manufacturer's instructions in CARAT laboratory, Adisseo, Commentry, France. The results showed that crude protein content was between 11.53–13.97 g 100 g^{-1} and in winter wheat varieties it was 9.68–11.00 g 100 g^{-1} dry matter. Analyses showed that starch content in spring and winter wheat varieties ranged from 53.29–58.67 and 60.51–63.89 g 100 g^{-1} respectively, crude fat in spring and winter wheat were 2.54 and 2.19 g 100 g^{-1} respectively, ash 1.71 and 1.69 g 100 g^{-1} respectively. Comparison of spring and winter wheat varieties grown in Lithuania suggests that varieties of spring wheat outperform winter wheat in protein, crude fat, ash and amino acids contents.

Keywords: *amino acids, wheat, chemical composition, grains, NIRS.*

Introduction

Wheat cereal grains are among the most important staple foods for the world's population. Near-infrared spectroscopy (NIRS) for determining grain chemical constituent contents has been studied over the past few decades around the world. The current visual methods for grain quality estimation are subjective and time consuming. The grain industry is in need of automated, economical, and rapid means of determining grain quality. Near-infrared spectroscopy has been used for moisture and protein contents of cereal grains (Delwiche, 2004), including wheat, in Lithuania over the past decade. However it has been reported that near-infrared spectroscopy may be used for moisture, starch, crude protein, crude fibre, and crude ash determination in cereal grains (Shenk et al., 1992). Application of NIR spectroscopy in qualitative analysis and NIRS is currently becoming more useful in cereal grain applications.

Wheat grading systems are commonly based on the wheat protein content (Williams, 2007; Hulasare et al., 2003). The price of wheat depends on the protein content, often with substantial price differences between grades. Grain chemical composition (including amino acids) of different cereal varieties depends on various factors such as grain size, sowing time (Kong et al., 2014), genotype, climatic conditions (Janušauskaitė et al., 2013), environment (Akçura et al., 2011), fertilisation, and soil conditions (Manès et al., 2012). NIRS is widely used in routine screening as it provides a quick, non-destructive assay requiring small or no sample pretreatment (Ferrio et al., 2000). The application of NIRS in wheat quality control has been characterized by rapid development from prediction of major constituents in wheat

grains (moisture, protein, fat, starch, ash) to prediction of functional properties (Williams, 2007).

It is important to investigate the chemical composition of wheats in a given geographic location because their nutritional value depends on variety, fertilization, environmental conditions. NIRS can be more efficient in the use of resources. Thus, the objective of this study was to determine the chemical and amino acid composition of wheat varieties grown in a location in Lithuania using NIRS methodology. It's not the first time that this methodology has been used in Lithuania, it's already a routine procedure in this country.

Materials and Methods

Grain samples of varieties of winter and spring wheat were collected from the Kaunas Plant Variety Testing Station (PVTS) – Sitkūnai (55°02′31″ N latitude; 23°48′50″ E longitude) grown in a location in Lithuania (Figure 1). Six spring wheat varieties - *'Cornetto', 'Diskett', 'Ethos', 'Rospuda', 'Sonett', 'Tybalt'* and six winter wheat varieties - *'Agil', 'Kovas DS', 'Mariboss', 'Mulan', 'Rigi', 'Zentos'*, were used in this study. Spring wheat fertilization was applied as $N_{16}P_{38}K_{76}$ additionally–N_{75}. Winter wheat fertilization was applied as $N_{11}P_{22}K_{55}$, additionally–$N_{68.8}$+$N_{68.8.}$ Soil parameters were: humus–1.65%, pH–7.6, P_20_5–140 mg kg^{-1}, K_20–327 mg kg^{-1}. During the experimental year (2014), the average temperature ranged from 8.9°C at tillering to 18.5°C at waxy maturity stage of cereals. Rainfall was between 1 and 100.2 mm per year during different development stages of cereal development (Alijošius et al., 2016).

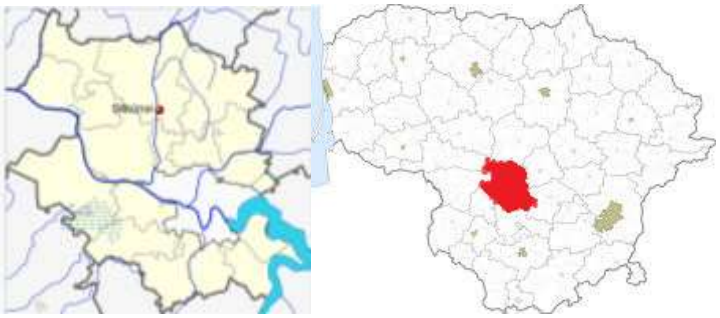

Figure 1. Map of the wheat sample collection region (red colour) in Lithuania

Wheat cereal grain samples (from each varieties 3 samples) were taken and analysed in accordance with the Commission regulation (EU) No 691/2013 of 19 July 2013, amending Regulation (EC) No 152/2009 as regards methods of sampling and analysis. Grain samples with three subsamples for chemical analyses were ground in an Ultra Centrifugal Mill model ZM 100 (Retsch GmbH, Germany) with a 1.0 mm sieve. Chemical compositions (dry matter, crude protein, crude fat, ash, crude fibre, starch, amino acids) were determined in spring and winter wheat by near-infrared spectroscopy (NIRS) without any previous sample pretreatment, except milling (CARAT laboratory, Adisseo, Commentry, France). Chemical composition was analysed using the FOSS NIRS™ DS2500 system according to the manufacturer's instructions.

The significance of differences between samples was established using one–way analysis of variance (ANOVA), and data are reported as means and standard deviations. Means were compared using Duncan's *t*-test ($P<0.05$). ANOVA was conducted using the statistical package SPSS 22.

Results and discussion

The chemical compositions of wheat varieties are shown in Table 1. About 70% of the bioavailable energy comes from carbohydrates, with starch being the most important fraction for animal nutrition (Klein et al., 2001). The majority of the carbohydrate content in cereal grains occurs as starch, which is readily digested (Franco et al., 1995; Hizukuri et al., 2006). Starch contents in analysed grain samples significantly differed between spring and winter wheat varieties ($P<0.05$). In spring wheat, grain starch contents ranged from 53.29 g 100 g^{-1} DM ('Ethos') to 58.67 g 100 g^{-1} DM ('Cornetto'). The highest starch content was determined in winter wheat variety 'Mariboss' (63.89 g 100 g^{-1} DM) and the lowest in 'Mulan' (60.51 g 100 g^{-1} DM).

Table 1. **Chemical compositions** (g 100 g^{-1} DM) **of the 12 spring and winter wheat varieties**

'Zentos'	86.78^{a}	11.00^{a}	2.24^{b}	1.69^{bc}	2.79^{bc}	61.14^{a}
Mean	**86.68**	**10.45**	**2.19**	**1.69**	**2.75**	**61.37**
SD	**±1.50**	**±0.54**	**±0.11**	**±0.03**	**±0.07**	**±1.26**

Means in the same column with different superscript letters are significantly different, $^{a-f}$ – $P < 0.05$, with spring and winter wheats tested separately.

The highest crude protein concentration was determined in spring variety 'Ethos' (13.97 g 100 g^{-1} DM) and the lowest in winter variety 'Mariboss' (9.68 g 100 g^{-1} DM). The winter wheat varieties accumulated less crude protein than spring varieties, differing overall by over 2%. Crude fat and ash concentrations were also higher on average, being 2.54 and 1.71 g 100 g^{-1} DM, compared with 2.19 and 1.69 g 100 g^{-1} DM overall for winter wheats. Mean crude fibre content present in this study in spring varieties ranged from 2.68 to 4.25 g 100 g^{-1} DM ($P<0.05$), but in winter varieties from 2.65 to only 2.82 g 100 g^{-1} DM.

Profiles of amino acids differed significantly between spring and winter varieties (Table 2). Eleven free amino acids were detected in the spring wheat and winter wheat samples; three from the aspartate family (Lys, Met and Thr), one from the glutamate family (Arg), three from the pyruvate family (Leu, Ile, Val), three from the aromatic amino acid family (His, Phe, Trp) and one from the 3 phosphoglycerate family (Cys). The ranges of amino acids in most wheat varieties were 0.12–1.07 g 100 g^{-1} DM. Wheat proteins are low in some amino acids essential to the human diet. Lys is a limiting amino acid in most cereal products and

during baking it is believed that Maillard reactions may affect the content and composition of related products lowering its availability (Charissou et al., 2007). In this study, comparing spring and winter wheats the lowest amount of lysine was found in the winter variety 'Mariboss' (0.27 g 100 g^{-1}) and highest amount in spring variety 'Ethos' (0.39 g 100 g^{-1}). High contents of phenylalanine (0.51–0.64 g 100 g^{-1}) and arginine (0.52–0.63 g 100 g^{-1}), and low levels of tryptophan (0.14–0.17 g 100 g^{-1}) were determined. Other amino acids, such as aspartic acid and glutamic acid, were not determined in this experiment. However, using RP-HPLC-FLD, Anjum et al. (2005) determined amino acid concentrations in flour to vary as follows: aspartic acid 0.453–0.841, glutamic acid 0.743–1.313g/100 g. Complementary results of Boila et al. (1996) gave leucine 1.04 g/100 g, arginine 0.695 g/100 g, and histidine 0.352 g/100 g.

Means in the same column with different superscript letters are significantly different, $^{a-f}$ – $P < 0.05$, with spring and winter wheats tested separately.

Conclusions

This study demonstrated that the chemical composition and amino acids differed significantly amongst six spring and six winter wheat varieties, determined with NIR spectroscopy. Comparison of spring and winter wheat varieties grown in Lithuania suggests that varieties of spring wheat outperform winter wheats in protein, crude fat, ash and amino acid contents.

Abstract

Morphological traits are of major importance in determination of the type of tobacco and varieties within the type. These traits differ to a lesser or greater extent and are genetically controlled. Under the influence of inadequate agro-ecological and technological conditions, tobacco types can also show strong variations in bio-morphological properties, especially in dimensions of the leaves. Such variations can occur despite the genetic control and are known as "plasticity" of tobacco. Therefore, before starting the production of some tobacco type or variety, it is necessary to know the basic preconditions for its stable production in order to avoid major variations in morphological and production characteristics. Three-year investigation 2009, 2010 and 2011 was carried out in the experimental field of Tobacco Institute – Prilep Republic of Macedonia. The trial was set up using the method of randomized blocks in 5 replications, with three varieties of Basma tobacco (MK-1, MB-2 and MB–3) and one Yaka variety (YK 7-4/2) as a check. The aim of investigation on morphological traits length, width and angle of the top and bottom leaf was to get a real picture of the varieties and their plasticity under the influence of different climate conditions. Research workers of the Scientific Tobacco Institute – Prilep created several varieties of Basma tobacco, including MK-1, MB-2 and MB-3, approved by the State Commission for variety testing in 2010, which yield and quality guarantee a cost - effective production. The creation of new tobacco varieties is a long-term commitment of the Tobacco Institute - Prilep and continuous process which has not been interrupted up to this day, giving a great contribution to the production. The significance of the trials was computed statistically and with the use of LSD test.

Keywords: *morphological traits, basma, length, width, leaf.*

Introduction

Oriental tobaccos Prilep, Yaka and Dzebel account for almost 95% of the total tobacco production in R. Macedonia. In recent years this stock has been enriched with Basma tobacco, which yield and quality meets the criteria and standards of manufacturers and companies that purchase tobacco from this region.

Of the 25-30 000 tons annual oriental tobacco production in R. Macedonia, over 90% are intended for exports. Republic of Macedonia is recognized as tobacco country small in size and population but one of the biggest in production of good quality oriental tobacco per capita. With the change of smoker's taste preference, the manufacturers requirements for particular raw materials of oriental tobacco used in cigarette blends also change. For these reasons, each year foreign buyers are offered raw materials of various types and varieties to satisfy their requirements in terms of flavor, taste and other properties of tobacco. The Basma tobacco is one of the most highly valued oriental tobaccos in the world. It is mainly grown in Greece and Turkey, but after the dramatic decline in these two countries (especially in Greece), tobacco companies see a chance to relocate a part of the production to the Republic of Macedonia, in areas where soil and climate conditions favor the production of this type. Leaf size in various years of investigation and with various amounts of precipitation show

that top leaves of Basma tobacco are typical representatives of oriental tobacco. According to the Rules for assessment and purchase of oriental tobacco, the top leaves are considered oriental if their size does not exceed 13 cm (Mitreski M., 2012). In order to make its production more attractive to manufacturers, the price of Prilep tobacco is slightly higher compared to other oriental tobaccos. Due to its quality, there are no problems with the export of this type and it gives incentive for production of newly created varieties which would be interesting for farmers, manufacturers, traders etc.

Materials and Methods

Four varieties of oriental tobacco were used as material for the three-year investigation (2009/2010/2011): YK 7-4/2 as a check (ø), and Basma varieties MK-1, MB-2, and MB-3. Seedling was produced in traditional way, in cold beds covered with polyethylene, in the experimental field of the Scientific Tobacco Institute - Prilep.

During the breeding process, all necessary cultural practices were applied: covering - uncovering, watering, fertilization and protection, simultaneously in all tested varieties, in order to obtain a healthy and well-developed seedlings. Fertilization was performed with 300 kg / ha NPK mineral fertilizer (8:22:20). The trials were set up using the method of randomized blocks with 5 replications, at 45 × 12 cm spacing on previously treated soil.

There were five rows in each plot, three of them were used for harvesting and two for protection and for morphological measurements. Leaf length and width were measured on 50 plants of each variety and the obtained data were statistically processed following the analysis of variance (ANOVA), using the LSD test. Meteorological data on the amount and distribution of precipitations in mm during the growing season May - September were obtained from the Meteorological Station at Tobacco Institute-Prilep.

Results and Discussion

Amount of precipitation

The requirements for water and warmth of each plant, especially of tobacco, are changing during the entire biological cycle. According to Atanasov D. (1962), tobacco plant requirements for water are variable and so the amounts of water should be gradually reduced during the vegetation period. The maximum precipitation for successful growth of oriental tobacco is 250 mm and the minimum is 100 mm, but since it is not sufficient for production of a good quality tobacco raw, additional irrigation is needed. The same author reported that the optimum precipitation during the field growth is 120 - 150 mm. According to Pelivanoska V. (2007), if there is only one rainy day in a month, with insignificant amount of rainfall per square meter, it should not be taken into consideration.

Nuneski R. (2008), in his trials with Izmir oriental tobacco in Turkey, reported that even low precipitations measured in July and August had a good impact on ripening and drying of the upper insertions, which are the main carriers of raw tobacco quality. In certain periods of plant growth, however, additional interventions with water were applied. Data in Table 1 show irregular distribution of rainfalls during the three years of investigation. Thus, the mean precipitation in May ranged from 55.0 mm in 2009 to 64 mm in 2010. During the vegetation period June – September, the lowest average precipitation by decades (0 mm) was recorded in July 2009 (third decade), June 2011 (third decade) and July 2011 (second decade), August 2010 (third decade) and September 2009 (first decade), when additional irrigation was applied depending on plant requirements.

The highest precipitation average was recorded in the third decade of June 2009 (68 mm). From June to September, the lowest mean monthly precipitation was recorded in July 2009 (8.0 mm) and the highest in June 2010 (87.0 mm).

According to the data presented in Table 1, the lowest amount of precipitation during the growing season (May-September) was recorded in 2011 - 180.0 mm, and the highest in 2010 - 298.0 mm.

Table 1. Amount and distribution of precipitations in mm (May-September) – location: Tobacco Institute – Prilep

Year	Decade	Months					Total precipitations May-September (mm)
		May	June	July	August	September	
2009	I	14.0	2.0	2.0	16.0	--	196.0
	II	1.0	5.0	6.0	4.0	13.0	
	III	40.0	68.0	--	23.0	2.0	
	Monthly	55.0	75.0	8.0	43.0	15.0	
2010	I	18.0	18.0	25.0	43.0	26.0	298.0
	II	17.0	47.0	8.0	2.0	1.0	
	III	29.0	22.0	23.0	--	20.0	
	Monthly	64.0	87.0	55.0	45.0	47.0	
2011	I	20.0	31.0	8.0	9.0	--	180.0
	II	32.0	20.0	--	1.0	23.0	
	III	11.0	--	9.0	1.0	15.0	
	Monthly	63.0	51.0	17.0	11.0	38.0	

Leaf size (length and width) of the undertop and top leaves of fresh tobacco

Data presented in Table 2 and Fig. 1 show that leaf length by years ranged from 10.3 cm in variety MK-1 in 2009 to 14.0 cm in MB-3 variety in 2010 and leaf width ranged from 5.4 cm in 2009 in MK-1 to 7.7 cm in Basma variety MB-3 in 2010.

According to the average values, the shortest leaf was measured in variety MK-1 (11.5 cm) and the longest in variety MK-3 (12.6 cm), which is 5% more compared to the check. In all three years of investigation, statistically significant differences at 1% were estimated in MB-3 variety in 2011, while other varieties did not show such differences. The smallest average width of the leaf was recorded in variety MK-1 – 6.3 cm and the largest in variety MB-3 – 6.8 cm, which is 6.25% more than the check variety. In the three years of investigation on the character leaf width, the investigated varieties did not show statistically significant differences. The increased amount of rainfalls in 2010 resulted in increased dimensions of leaves, but still within the permitted range.

Top leaves are the smallest leaves of tobacco plant. They are characterized by a sharp apex and the broadest leaf base (Fig. 2). The largest width is measured at the base of the leaves and they account for 6-7% of the total yield of the stalk.

Figure 2. Top leaves of fresh tobacco

According to data in Table 3, the variety MB-3 had the smallest length of the top leaf in 2009 (8.1 cm) and the biggest length in 2010 (12.9 cm).
The shortest top leaf was measured in the variety MK-1 (9.6 cm), and the longest (10.5 cm) in varieties YK 7-4/2 (∅) and MB-3. The tested varieties did not show statistically significant differences during the three years of investigation.
Leaf width ranged from 4.8 cm in MK-1, MB-2 and MB-3 in 2009 to 7.1 cm in MB-3 variety in 2010. The average width of the top leaf ranged from 5.5 cm in MK-1 to 5.9 cm in the check variety YK 7-4/2 and MB-3. No statistically significant differences were recorded in the investigated varieties with regard to this trait.

Based on the results of the three-year investigation on morphological traits of oriental Basma tobacco in the Republic of Macedonia, the following conclusions can be drawn:

Conclusions

- The trial was set up on colluvial-diluvial soil, with low humus and nitrogen content and good supply of available phosphorus and potassium. The use of mineral fertilizers (300 kg/ha N8:P22:K20) is a guarantee for obtaining higher yield and good quality.
- The amount of precipitation during the growing season May-September ranged from 180.0 l/m^2 in 2011 to 298.0 l/m^2 in 2010. Due to the uneven distribution of rainfalls in this period, it was necessary to apply additional water interventions in the field.
- The smallest length of the undertop leaf was measured in variety MK-1 – 11.5 cm and the largest in variety MK-3 – 12.6 cm, which is 5% more compared to the check variety. During the three-years investigation, statistically significant differences at a level of 1% were recorded in MB-3 variety in 2011 and no such significance was observed in other varieties.
- The smallest leaf width of the undertop leaf of 6.3 cm was measured in MK-1 variety and the largest width of 6.8 cm was recorded in MB-3, which is 6.25% more than the check variety.
- The length of the top leaf ranged from 9.6 cm in variety MK-1 to 10.5 cm in the check variety YK 7-4/2 and in MB-3. The investigated varieties did not show statistical significance in the three years of investigation.
- The average width of the top leaf ranged from 5.5 cm in MK-1 to 5.9 cm in the check variety YK 7-4/2 and in MB-3. With regard to this trait, the investigated varieties did not show statistically significant differences compared to the check variety. According to the results obtained, the MK-1 variety is characterized by the smallest length and width of the top leaf.

- The results of the three-year investigation under variable amounts and distribution of rainfalls indicate that the top leaves of Basma varieties in the region of Prilep are typical of the oriental type of tobacco.

Abstract

Pomegranates are valuable fruits due to the high level of anthocynanins in juice and phenolic compounds responsible for antimicrobial activity of pomegranate peel. Significant amounts of phenolic acids, vitamin C and other polyphenolics are responsible for health benefits of the consumers. The objects of our study was the impact of variety on the quality of pomegranates grown in the region of Macedonia. More precisely, morphological parameters for fruits and chemical characteristics of pomegranate juice were significantly affected to the variety of pomegranates. Morphological parameters, in particular fruit weight, fruit height, equatorial and calix diameter favorited "Hicaz" variety in comparison to autochthonous "Karamustafa" variety of pomegranates. Furthermore, the pH value of fruit juice, the level of phenolic acid and percentage of glucose and fructose indicate significant differences between varieties. The quantity of anthocyanins (537 mg/L), catechins (50 mg/L) and total phenolic compounds (3367 mg/L) indicated higher quality of pomegranate juice from "Hicaz"pomegranate variety. The effect of pasteurization did not influenced significantly to the quality of pomegranate juices from both varieties.

Key words: *pomegranate juices, morphological parameters, total phenolic compounds, anthocyanins, catechins*

Introduction

Pomegranates are valuable fruits due to the level of anthocynanins in juice and phenolic compounds responsible for antimicrobial activity of pomegranate peel (Dimovska *et al*., 2018). Significant amounts of phenolic acids, vitamin C and other polyphenolics are responsible for health benefits of the consumers (Dimovska *et al*., 2017).

Pomegranates are native from Persia and it is believed that the origin is in Central Asia. The morphological changes might have occurring during domestication and the most indicative changes are usually notice on flower, rind and aril colour, fruit size, percentage of sugar and organic acids as well as quality of the seeds (Teixeria da Silva *et al*., 2013)

The objects of our study were the impact of variety on the quality of pomegranates grown in the region of Macedonia. More precisely, this study examined the effect of variety on morphological parameters for fruits and chemical characteristics (Brix, pH, organic acid, total phenolic compounds, catechins and anthocyanins) of pomegranate juice from the autochthons varieties "Karamustafa" and "Hicaz".

Materials and Methods

Sample preparation

The sampled fruits were selected randomly in order to separate three replicates for analysis, using 20 kg per repetition and cultivar. Pomegranates were weighed, cut in halves, and arils were hand separated from the pith avoiding contamination by components in membranous walls (septum). Juices of each culivar were obtained by pressure of arils and weighed to determine the juice yield. Samples of freshly prepared juice from both varieties ("Hicaz" and "Karamustafa") were stored frozen one year (−20 ◦C) until have been analyzed.

Physical properties

Size of the randomly selected 100 dried arils was determined from the axial dimensions of arils. Length was measured using a digital caliper at the accuracy of 0.01 mm. Weight of the hundred dried arils was determined by randomly selecting five samples and weighing in an electronic balance of 0.001 g sensitivity.

Chemical analyses

For determination of titratable acidity (TA), 2 ml of fresh juice was diluted with 70 mL of distilled water and titrating with 0.1 M NaOH to an end point of pH 8.2 using a Metrohm 862 compact titrosampler (Herisua, Switzerland). The results were expressed as percentage of citric acid (% CA). Total soluble solids (TSS, °Brix) was measured using a digital refractometer (Atago, Tokyo, Japan) calibrated with distilled water. The pH values were determined at room temperature using a calibrated pH meter (Crison, Model 00924, Barcelona, Spain). All measurements were made by three repetitions

The total phenolic content of pomegranate juices was determined with Folin–Ciocalteau reagent. For each sample, 50 μL of diluted (1:5) oil extract were added to 750 μL water and 50 μL of Folin–Ciocalteu reagent. The solution with total volume of 850 μL was incubated in the dark for 5 min. Then, 150 μL of 20% sodium carbonate solution was added and samples were incubated in the dark for 1 h. Reference solution was prepared with distilled water instead pomegranate juice and treated with the Folin–Ciocalteu reagent in the same way as the assayed samples. The samples turned to a blue colour with different degrees, depending on the content of phenolic compounds in the samples. The absorbance at 765 nm was recorded against the absorbance of the reference solution. The color intensity was measured spectrophotometrically by UV/VIS spectrophotometer (Shimadzu 1800, Shimadzu corporation, Kyoto, Japan). Determination of monomeric anthocyanins was performed by the colorimetric method of Singleton and Rossi (1965). The measurements were performed by three repetitions

Results and discussion

The chemical parameters of the samples of pomegranate juices from two varieties are presented in Table 1. As we can see, there is no significant difference between results obtained for Brix and pH for both pomegranate varieties. Furthermore, there is no statistical difference between pasteurized and fresh pomegranate juices. On the other hand, there is significant difference between the level of organic acids, monomeric anthocyanins, total phenolic compounds (TPC) and total catechins which were higher for "Hicaz" variety in comparison to "Karamustafa" variety.

Data from physical and morphological characterization of pomegranates from "Hicaz" and "Karamustafa" varieties from 2016 and 2017 vintage years are presented in Tables 2 and 3. The pomegranates from "Hicaz" variety had higher average fruit weight. Percentages of grain and peel were higher for "Karamustafa" variety as well as weight of 100 berries and percentage of skin. The percentage of carpels was more than double for "Hicaz" variety as well as equatorial and calyx diameter and fruit height with and without calyx (Table 3). Pomegranates from "Karamusfata" variety had reddish yellow colour of the fruit and pink colour of the fruit juice. On the other hand, pomegranates from "Hicaz" variety had reddish colour of the fruit and dark pink colour of the fruit juice (Table 1 and Fig.1.). The average fruit weight of pomegranates from "Hicaz" variety was the same as "Chioukhi" variety of pomegranates from Morocco. On the other hand, calix diameter for "Hicaz" variety of pomegranates was similar to Moroccanish "Ounk Hmam" variety and calyx for "Karamusfata" variety was more similar to some Spanish varieties of pomegranates [5].

D1-equatorial diameter, D2 – calyx diameter, L1 – fruit height without calyx , L2 – total fruit height, L3 – calyx height,

Conclusion

The purpose of the present study was to evaluate the morphological, physical and chemical parameters, in particular organic acids, total phenolic content (TIC), catechins and anthocyanins in two varieties of pomegranates juices from the region of Macedonia. The lower level of phenolic compounds and acids as well as catechins and anthocyanins had pomegranate juice from the autochtonous variety "Karamustafa" and the higher level had the pomegranate juice obtained from "Hicaz" variety. Based on the explanation above, we can summarize that pomegranate juice from "Hicaz" variety is enough rich source with polyphenolic compounds. Finally, we recommend the juice from this pomegranate variety for further investigation in order to identify and quantify the level of polymer compound and other valuable bioactive compounds with significant impact on human health.

Abstract

The feijoa (*Acca sellowiana*) is a fruit tree recently grown in Mexico, where trees had been established in humid tropical highland conditions of Veracruz, at 1900 m of altitude. Industrial potential of feijoa at the moment are unknown. The objectives of this study were to determine aromatic compounds in the skin of the fruit, oils in the seeds, and some physical and chemical characteristics in the pulp. Commercial-sized fruits were obtained from eight-year-old trees with a single compost application per year and without artificial irrigation. Feijoa seeds had 69.4% unsaturated fatty acids, mainly linoleic (46.2 %) and linolenic (3.7). The major compounds in the essential oil of the feijoa skin were benzoate 2-methylpropane and caryophyllene acids with 18.41% and 10.28 %, respectively. The total dry mater, humidity, ash, proteins, ethereal extract, crude fiber in the pulp differed slightly from those reported in the literature of feijoa cultivated under temperate conditions. The feijoa fruit produced under tropical highland conditions is adequate as a fresh commodity and for making industrial food products.

Keywords: *Acca sellowiana, essential oils, fruit skin, oil in seeds, isobutyl benzoate.*

Introduction

The feijoa is a new fruit tree crop in Mexico, and the few agronomic experiences with this Myrtaceae are found in the humid tropical highlands of Veracruz at 2000 m of altitude where precipitation is around1900 mm per year, with annual average temperature of 17 C. Feijoa center of origin is located in the highlands of Paraguay, southern Brazil and Uruguay, and northeastern Argentina (Keller & Tressens, 2007). In New Zealand and Australia, feijoa cultivation has been very popular and the fruits are exported as fresh fruit or industrialized products. Its cultivation has increased in Italy, China and Turkey due to its high market sales potential and its medicinal anticancer, anti-inflammatory, antiviral, antimicrobial, hepatoprotective, anti-osteoporosis, antihyperthyoid, antioxidant and immunomodulatory properties (Lim, 2012). The feijoa is also used as a preventive treatment for gastritis and ulcers (Monforte *et al*., 2014). However, the information about fruit composition and specifically on oils in the seeds, and essential oils in the skin of feijoa under tropical highlands conditions is limited. The essential oils are volatile substances of organic nature, responsible for the aroma of plants, and the term of oil is not related to fats. Some of the feijoa volatile compounds are the methyl and ethyl benzoates, which represent approximately 90% of the volatile fraction and are responsible for the aroma of the fruit (Binder & Flath R, 1989). Regarding to the oil content of the feijoa seeds, Andrade *et al* (2012), obtained a yield of 1.5% of lipids in 100 g of feijoa seeds. The composition of the oils in the feijoa varies according to its geographical origin (Weston, 2010). The objectives of this study were to determine some physical and chemical properties in the pulp of the fruit, and determine oils in the seeds, and essential oils in the skin of the fruit. This is the first report regarding oils in the seeds of feijoa, and essential oils in the skin of feijoa fruit produced under tropical highland conditions.

Materials and methods

Plant material. All the fruits evaluated were harvested at physiological maturity and harvested in an orchard located at 2000 m of altitude in Veracruz, Mexico. All the trees were seedlings planted at 4 x 4 m that received water from the rain.

Bromatological analysis. Total moisture, total dry matter, ash, crude protein, ether extract, crude fiber and carbohydrate percentages were determined in 10 ripened feijoa fruits harvested in each of four accessions that were propagated by seed. The determinations were carried out in accordance with several Mexican standards for the bromatological analysis of food.

Oil in the seeds. In fruits randomly harvested a total of 30 g of seeds were extracted. The oil of the seeds was obtained using an instrument of destilation Soxhlet (Meyer *et al*., 2008). The fatty acid profile was determined by gas chromatografy (Agilent 6890) with a coumn AT-FAME (López-Yerena *et al*., 2018).

Essential oils. They were isolated from the fruit skin using the Clevenger device. The essential oil was analyzed in a gas chromatograph coupled to an Agilent 7890 B ion trap. A capillary column (30m x 250 µ x 0.25 µ) was used for the separation.

Data analysis. A completely randomized design was used to evaluate the physical and chemical characteristics of the fruits. The variables were evaluated with an analysis of variance and significant differences among means were determined using the Tukey test ($P \leqslant 0.05$). Standard errors were also determined. Data analysis was done with the InfoStat statistical package (Di Rienzo et al., 2016).

Results and discussion

Bromatological analysis

There were significant differences ($P \leq 0.05$) among the four accessions propagated by seed in all the physical and chemical variables evaluated (Table 1). The total moisture, ash, crude protein, ether extract, crude fiber and carbohydrates was slightly different from the values found by González-García *et al.* (2018), using other seedlings of feijoa receiving a different amount of precipitation in Veracruz, Mexico, or with selected feijoas in Colombia (Fischer *et al*., 2003). The total dry matter of the fruit (%) (Table 1) coincide with the 15±1 % reported by Sun-Waterhouse et al (2013) in New Zealand. The dry matter content determine quality in fruits (Famiani *et al*., 2012). Thus, in general these parameters changed little in the feijoa fruit produced under a tropical highland condition. Likewise, fruit size values of feijoa grown in a tropical conditions are adequate for the market (González-García *et al*., 2018).

Oil content of the seeds

The content was of 0.23 %, and this value was two times lower than the reported by Andrade *et al.* (2012) in Brazil with feijoa trees grown under temperate conditions. The linoleic acid achieved the highest value with 46 % (Table 2), and Andrade *et al.*, (2012) also found the linolenic acid (84%) as the main fatty acid in the feijoa seeds. In this work it was confirmed that the linoleic acid is the main fatty acid in the seeds of feijoa. The palmitic acid had 21 %, and the oleic acid 19 % (Table 2). Lower values has been reported for the oleic (Andrade *et al*., 2012) in comparison with those found in the present study. Most of the fatty acids (69 %) in the seeds were polyunsaturated.

Essential oil

The yield of the essential oil obtained from the feijoa skin was of only 0.3%. Low essential oil recoveries have also been obtained in New Zealand (Shaw *et al*., 1983). There were 57 compounds detected. The isobutyl benzoate or benzoic acid 2-methylpropyl ester (numbers 29 and 57 in Table 3) achieved the highest content (18.41%) followed by the caryophyllene oxide (10.28%) (number 22 in Table 3). Two important volatile components of the feijoa fruit are methyl benzoate and ethyl benzoate (Hardy and Michael, 1970), then the isobutyl

benzoate (Table 3) plays an aromatic role because this compound belongs to the family of benzoic esters. The caryophyllene oxide, is a natural bicyclic sesquiterpene present in many essential oils. Saj *et al*. (2008), reported that the feijoa essential oil had a broad spectrum of antibacterial and antifungal activity due mainly to the caryophyllene oxide. Another compound identified was azulene (4.53%), and some derivatives of azulene prevent gastric lesions (Amagase *et al*., 2013). Feijoa fruit produced under tropical highland conditions of Veracruz are less aromatic than the produced in New Zealand. The % of the caryophyllene oxide was lower than the found by Saj *et al*. (2008). It seems that the environment conditions where our fruit grew influenced negatively the production of essential oils in the skin.

Conclusions

Some chemical characteristics such as total dry matter, total moisture, protein, carbohydrates, fats, ash and fiber of feijoas harvested in Veracruz, Mexico, were comparable with values reported in other countries where feijoa is cultivated under temperate conditions. The main oil in the seeds of feijoa was the linoleic acid. Then main essential oils were benzoic acid 2-methylpropyl ester and the caryophyllene oxide. The trees used in this study were propagated by seed and varied among them in fruit chemical characteristics then trees well adapted for tropical highlands require be selected. The skin of the feijoa containing essential oils and other chemical properties could be used in the alimentary industry..

MORPHOLOGICAL CHARACTERISCS OF FRUITS AND PITS OF SOME JUJUBE (*ZIZIPHUS JUJUBE* MILL.) GENOTYPS

Miroslav ČIZMOVIĆ*, Ranko PRENKIĆ

Biotechnical Faculty Podgorica, Montenegro
*Corresponding author: miroslaw@t-com.me

Abstract

During the two consecutive years (2015-2016) the main morphological characteristics of jujube fruits and pits of three cultivated and three 'domestic' genotypes were studied. The research was carried out on three well known cultivars ('Lang', 'Li' and 'Tsao'), and three domestic genotypes with higher fruit weight. The highest weight of fruit (24.32 and 23.97 g) was registered in cultivars 'Lang' and 'Li', statistically significantly higher compared with other cultivars and genotypes. Cultivars with higher weight of fruit ('Lang' and 'Li') also had the highest weight of flesh (23.57 and 23.03 g), and weight of pits, although the smallest weight of pit was registered in cultivar 'Tsao'. The highest flesh to stone (pit) ratio was registered in all cultivated cultivars ('Lang' 96.87%, 'Li' 95.95 % and 'Tsao' 95.15%), mostly due to the higher mass of flesh. Also, 'Tsao' cultivar had the smallest mass of pit (0,40 g), statistically significantly smaller than other cultivated cultivars, and domestic genotype 3. Statistically highly significant correlation between the weight of fruit and the weight of the flesh (r=0,986**), and the pit (r= 0,929**) was found. Morphological characterization can be first step in future breeding program for improvement domestic genotypes aiming to increase fruit size, and keeping the quality of fruit.

Keywords: *morphological characteristic, jujube, Ziziphus jujube Mill.*

Introduction

Jujube, also known as Chinese date, is the deciduous subtropical fruit species from family Rhamnaceae. Jujube's fruit belongs to drupe type with single hard pit (stone). It is considered to be resistant to winter cold (Lyle, 2006) and other unfavorable ecological condition (arid environment, saline soil etc). Jujube grows as a small-medium tree (2-5 m high) with very hard and strong wood, although it sometimes forms a bush.

It originates from the regions of the middle and lower reaches of the Yellow River (China), and is often referred to as Chinese date (Yao, 2012). It is mostly cultivated in China, where this species extends over 200.000 ha and more than 400 cultivars is registered (Lyle, 2006). According to recent data, China has 700-800 cultivars of jujube (Yao,2012). Some of them are used for fresh consumption, but also some cultivars are good for processing (drying, candied) or as an ornamental tree. China is the largest producer with 90% of the total world production (Zheng at al., 2010).

According to some allegations in our region jujube was known 2.500-3.000 years ago, and it is believed that have been brought from Syria (Nikolić and Radulović, 2010). There are no plantations, but in the coastal region and its hinterland it grows in the gardens and yards. It can be considered as a true ecological fruit since no cultural practices are applied. Fruits of this species can be found on the market from the end of August to the half of October. Domestic people prefer jujubes with crisp and sweet taste of flesh, what is the case in period when the fruit was half colored in dark brown. Since the production is very small, virtually everything is sold on the local market.

In Chinese folk medicine jujubes have been used as a very important plants due to its helty-beneficial efects (Gao et al., 2012). Jujube fruits are reach in fibre, minerals, sugars, organic and phenolic acids, and especially in vitamin C (Gao et al., 2012, Li et al, 2007).

The genetic diversity of this species grown in Montenegro is unexplored. The aim of this paper is to compare morphological characteristics of jujube with larger fruits compared to commercial cultivars. This can be the first step in selecting and promoting potentially interesting genotypes for propagation.

Materials and methods

The research comprised 6 jujube genotype during two consecutive years (2015-2016). Three researched genotypes are introduced cultivars 'Li', 'Lang' and 'Tsao', and three genotypes are choosen from domestic population with larger friuts. The research was carried out at the Tomba locality in Bar Municipality, Montenegro. Each genotype is represented by one tree.

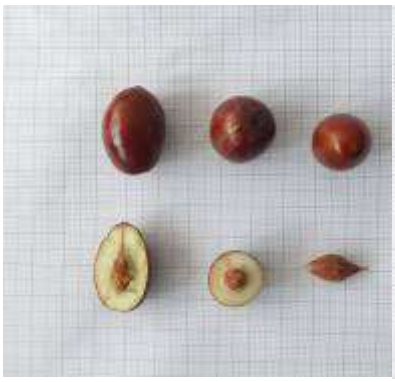

Figure 1. 'Domestic 1' genotype

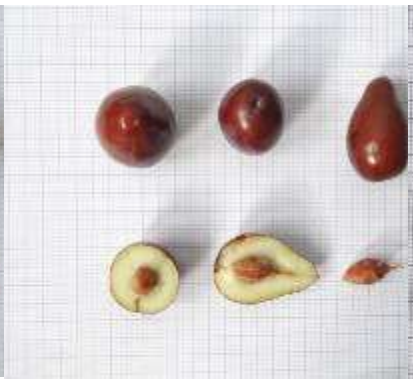

Figure 2. 'Domestic 2' genotype

Figure 3. 'Domestic 3' genotype

Figure 4. 'Li' cultivar

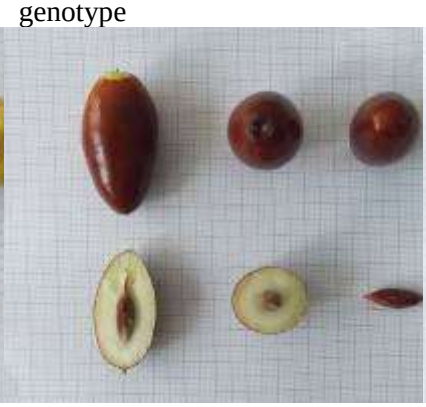

Figure 5. 'Tsao' cultivar

Figure 6. 'Lang' cultivar

The fruits for analysis were harvested when the epidermis of fruits were 50% colored in dark brown and the flesh was crisp and sweet (Stage 85, Hernandez et al., 2015). The following parameters were tested for morphological analysis: fruit weight (FW), flesh weight (WF), fruit length (FL), maximum width (MW), smallest width (SW), pit weight (PW), pit lenght (PL), pit width (WP) and ratio fruit/pit weight (RF). Fruit weight and pit weight were measured by digital balance "E Mettler" with an accuracy of 10^{-2} g. The dimensions of fruit and pit were measured by digital caliper with a precision of 10^{-2} mm. The data were tested by one-way analysis of variance and the significance of differences of means was tested by the LSD test for the levels of significance 0.05 and 0.01. The correlation among variables was calculated according to Pearson's correlation matrix for all studied parameters. Coefficient of determination was calculated as a square of correlation (Hadživuković, 1991).

Results and discusion

Fruit size, color and shape of fruit are the main attributes that attract customers' attention. This is mostly influenced by genetical potential, environmental conditions and yield. Although the weight of fruits contribute to higher yield, this is not the only factor for evaluating cultivars.

Table 1. Comparison of means (LSD) for main characteriscs of fruit of jujube genotypes

Factors Cultivars	Fruit weight FW (g)	Flesh weight WF (g)	Fruit lenght FL (mm)	Max. width MW (mm)	width SW (mm)
'Domestic 1'	4.63 c*	4.19 c	28.65 c	18.80 d	18.05 d
'Domestic 2'	4.04 c	3.63 c	29.16 c	19.66 d	18.65 d
'Domestic 3'	6.52 bc	5.99 bc	29.59 c	21.67 c	21.28 c
'Li'	23.97 a	23.03 a	39.01 b	36.60 a	33.79 a
'Tsao'	8.29 b	7.90 b	40.14 b	21.83 c	20.94 c
'Lang'	24.32 a	23.57 a	46.42 a	34.85 b	31.69 b
Critical values for comparison					
$LSD_{0.05}$	3.8044	2.6556	3.0252	1.5627	1.8948
$LSD_{0.01}$	2.6831	3.7654	4.2895	2.2157	1.3363
* The letters indicated differences at 0.05 level of significance					

The fruits of the highest weight were registered in the cultivars 'Lang' and 'Li', statistically significantly higher than in other studied cultivars. The genotype 'Domestic 3' has moderately large fruits, a little bit smaller than the 'Tsao' cultivar. Variations in the mass of jujube fruit are stated by many authors (Grygorieva et al., 2014, Hernandez et al., 2016, Markovski and Velkoska-Markovska, 2015). According to these authors, the weight of the fruits of some cultivars varies from very low mass (2.8 g,), to very large 29.3 g.

The quality and taste are factors that are more difficult to determine (Crisosto et al., 2010), but it is obvious that most authors from countries of similar ecological conditions (Spain, Macedonia) reported similar consumers demands in terms of fruit quality. Also, smaller fruits can have a higher nutritional value (higher content of vitamin C), compared to cultivars of larger fruits (Markovski and Velkoska-Markovska, 2015). Particularly appreciated is the crispness of the flesh. The cultivars of the largest weight of fruit ('Lang' and 'Li') have the largest mass of flesh This characterstic is determined by a relatively small mass of the pit, so the flesh of the friut has the highest importance for the fruit's size. This can be registered from the results of the correlation dependence analysis (Table 3). The weight of the flesh has a statistically significant effect on the mass of the fruit (r = 0.9984), and according to the coefficient of determination mass of fruit is 98 % determined by the mass of flesh. Length and width of the fruit are characteristics that determine its shape. The fruit shape can be round, oblong, oval, ovate, obovate, oblate or abnormal shapes (Yao, 2012). Our genotypes mostly have an elongated-ellipsoidal shape. The friuts of 'Li' cultivar have an apple-like shape, while the 'Lang' cultivar is pear-shaped. The biggest difference between MW and SW is registered in cultivar 'Lang'. Due to this, the 'Lang' cultivar at the cross-section has an ellipsoidal shape, while other studied cultivars mainly have a round shape.

Table 2. Comparison of means (LSD) for main characteriscs of pit of jujube genotypes

Factors Cultivars	Pit weight PW (g)	Pit lenght PL (mm)	Pit width PW (mm)	Fruit/pit ratio RF (%)
'Domestic 1'	0.44 d	18.92 c	7.54 d	90.31 cd

'Domestic 3'	0.53 c	18.56 c	8.14 bc	91.73 c
'Li'	0.93 a	22.87 b	9.84 a	95.95 ab
'Tsao'	0.40 d	23.84 b	6.68 e	95.15 b
'Lang'	0.76 b	29.76 a	8.53 b	96.87 a
Critical values for comparison				
$LSD_{0.05}$	0.0551	2.3393	0.5092	1.5704
$LSD_{0.01}$	0.0781	3.3170	0.7220	2.2268
* The letters indicated differences at 0.05 level of significance				

The folk name for Jujube in Montenegro is "iglica" which means needle. The name was given by the narrow and long pit inside the fruit. Cultivars with higher weight of fruit have a higher average weight of pits ('Li' and 'Lang'). The exception is the 'Tsao' cultivar which has the statistically significant smallest mass of pit (0.4 g). This is probably caused by the smallest width of the pit. Due to the higher weight of the fruits cultivars 'Lang' and 'Li' have statistically significantly higher fruit/pit ratio in comparision with other cultivars. This is a consequence of a larger difference in the weight of the fruit, while the variation in the weight of the pit is significantly lower. Similar results were reported by Grygorieva et al. (2015) and Sulusoglu et al, (2014).

$p < 0.05$ * statistically significant

$p < 0.01$ * statistically highly significant are indicate in bold

The studied characteristics of morphological traits have shown certain statistically significant correlation dependencies. As already mentioned, the most significant correlation dependence is recorded between the weight of the friut and the weight of the flesh. The weight of the friut is statistically significantly correlated in relation to the fruith width (both MW and SW) and the mass of the pit. The length of the pit is in a statically significantly correlation dependency by the length and especially the width of the fruit. Regarding to this characteristic, 'Tsao' cultivar is an exception, because it has a smaller width of the pit which significantly reduced its weight. According to the results given in Table 3, the fruit/pit ratio most dependens on the length of the fruit. Similar results of correlation dependency are stated by Grygorieva et al. (2014). According to these results, the weight of the fruit is determined by the width of the fruit ($r = 0.97$) and the fruit length ($r = 0.77$).

Conclusions

Jujube production in Montenegro is at a low level and does not meet the needs of the local population. Genetic diversity of this species has not been studied, but it can be assumed that there are potentially interesting genotypes. Jujube as a species can be grown on land that is not suitable for cultivation of other fruit species, so it is necessary to research the existence of other jujube genotypes with preferable fruit characteristics. One of them could be genotype 'Domestic 3', which has a satisfactory weight of fruit and taste, and should be recommended for multiplication.

Abstract

Lately, the number of people suffering from gluten-based foods is increasing. Therefore, dietary foods that contain gluten have become very popular, especially among people who do not have any problem with gluten tolerance. With a properly selected cereal type, knowing their qualitative properties, it is possible to make a balanced diet for the population with diagnosed gluten intolerance. The conducted study covers seven types of commercial cereal genotypes as soft wheat, durum wheat, barley, rye, oats, millet and brown rice. Durum wheat grains are the richest in proteins (13.31 g 100 g^{-1}) and fat poorest (1.84 g 100 g^{-1}). The same species had also the highest wet gluten content 26.33 g 100 g^{-1}, while in the barley it was the lowest (8.19 g 100 g^{-1}). Regarding the dry gluten, the highest value is found in soft wheat grains (14.81 g 100 g^{-1}) and at least in rye (3.03 g 100 g^{-1}). Differences between investigated commercial cereal cultivars regarding quality traits are statistically significant.

Key words: *cereal grains, genotypes, gluten intolerance, nutrition, quality.*

Introduction

One of the most important tasks of modern agriculture is to provide enough food for an ever-growing population. Cereal grains and products derived from them represent an important component in human nutrition both in developed and in developing countries. Cereals constitute basic food for humanity and represent the main constituent of animal feed (Koehler, Wieser, 2013). Almost two thirds of the total daily intake of carbohydrates originates from them. They are grown on nearly 60% of the cultivated land in the world. Today, humanity has a range of grains from various commercial cereals, and also are added grains that have no grain origin. The habits of consumers are changing, so the area under alternative cereals in the world is growing slowly. High content of carbohydrates makes cereals suitable as an energy source because of fast digestion and the energy released for the body. In developed European countries annual consumption of cereals varies and ranges from 60-80 kg per capita (Mickovski-Stefanović et al., 2012). Among them, wheat is the most important. White flours are the most important grain products. Soft wheat is our most important bread cereal. According to the statistical data, wheat bread today represents a big part of the diet for more than 70% of the planet's population. The protein content of cereals is high in the case of durum wheat, soft wheat, oats, barley and rye, where proteins are higher than 10.0% represented. Bearing in mind that the daily recommended protein intake is 0.8 mg g^{-1} thereby mix of cereals (Damgaard et al., 2013) with nuts is an excellent source of essential components for the start of the day (Jablonskytė-Raščė et al., 2013). On the other hand, the amount of fat is low and therefore in the risk groups of populations with hyperlipidaemia, cereal intake, especially durum and barley is recommended. Cereals contain significantly less protein than leguminous grains with 20.00% to 40.00% leading on the list of vegetable protein source (Bartkienė et al., 2016). This fact is valuable not only for the human population but also for animal (Gonzalez, 2015). Even in the preparation of ready-made flour, a bean starch is used for the preparation of gluten-free bread (Krupa et al., 2010). In the grain 95% of the

proteins are represented by gluten, which is a complex composed of gliadins (prolamines) and glutenins (glutelines) (Žilić, 2011). Certain populations of people are intolerant on gluten having digestive problems and allergic reactions particularly on gliadins and many suffer from celiac disease which is a serious illness and requires a special dietary regime. Gluten intolerance does not know age limits (Miyazaki et al., 2006), so it occurs in babies and young children and in adults at different age. It is important to mention that the amount of gluten in the cereals has changed and went through an evolutionary pathway, as evidenced by the research carried out by (Bustamante et al., 2017). Addressing the gluten intolerance and possibility to achieve a balanced diet (Dickey, 2008) is a complex and frequently asked question. This research problem sometimes depends on cultural beliefs and dietary habits (Ferrari, 2014).

With a carefully selected cereal type and making a choice between commercial cultivars, it is possible to make a balanced mix for populations that show any allergic reactions, but also for those with accurately diagnosed gluten intolerance (Newton et al., 2011). It is especially important to keep in mind that some of the cereals, such as oats and rice are gluten-free and they are excellent foods which are rich in fibres. This opens new perspectives on reducing or avoiding an incorrectly balanced meal and ensuring a functional diet, respectively. Therefore, the goal of this research was to determine the quality properties of seven types of genotype commercial cultivars pointing out which cereal contains most proteins that appear as allergenic gluten-based ingredients.

Materials and methods

Plant material. The investigations involved seven types of cereals: soft wheat, durum wheat, barley, rye, oats, millet, brown rice and polished rice. For each type of commercial cereal cultivars were purchased 30 samples in 2017 from different places like supermarkets, green markets, healthy food stores and organic food stores. From healthy food stores were purchased 1.00 kg of bulk package. Regions and cities were carefully selected to cover almost the entire territory of the country as following Skopje, Veles, Shtip, Kochani, Strumica, Prilep and Ohrid in Macedonia. Cleaned and dried up to reaching 11.0% grain moisture samples were put in fridge as short-term stored in glass jar under 4°C. Each sample of commercial cultivars was manually cleaned and put in plastic jar and tempered separately maximum to 14.0% moisture. All samples were kept under ambient temperature for 24 hours. From each of samples were measured ten sub-samples with weight of 100.00 g seeds in order to obtain a well-balanced analytical sample.

Laboratory analysis. All samples were analysed for moisture, protein, fat, fibre, wet and dry gluten content in whole grains g 100 g^{-1} dry mass (DM) according the standard recognizable accredited methods (http://www.iarm.gov.mk/files/Akreditirani-tela/Laboratorii/OB05-25_LT-036.pdf). The content of the protein is determined as nitrogen content according to Kjeldahl method (conversion factor to protein 6.25), fat content by Soxhlet method, crude fibre according the method of determining and calculating by Kürschner-Hanak method and gluten by a grain analyser "Infratec 1241 Foss" with a calibration package IM 9200 ("Foss", Denmark). Moisture content was determined by drying of plant material at 105 ± 2°C to constant weight (ICC 109/01:1976 - Determination of the moisture content of cereals and cereal products).

Statistical analysis. The obtained data were statistically analysed by one-way analysis of variance (*ANOVA*), statistical program *SPSS*. Differences between cereal grains concern quality traits are considered $P < 0.05$ and $P < 0.01$.

Results and discussion

With respect to structures and amount of chemical constituents, very significant differences exist between cereals and even between cultivars within each cereal. These differences in a large extent determine the quality of products made from cereal grains (Koehler, Wieser, 2013). Regarding the ambient conditions under which were kept grain samples the moisture content almost does not show larger variations. Regarding commercial cultivars, the highest average moisture content was found in durum wheat 12.64% DM and the millet is characterized by the lowest 10.73% DM (Table 1).

Table 1. Moisture content (%) and quality of analysed grains (g 100 g^{-1} dry mass) * at commercial cultivars

Note. * – data expressed as means (n = 30 ± SD), **GF – gluten-free.

Among the analysed samples for each cereal (n = 30), the biggest differences were recorded in the grains of polished rice 4.18 (13.3–9.12), and most of the moisture was found in an oat sample 13.94% DM, while in millet grains at least 12.68% DM (Fig. 1).

Proteins, after carbohydrates, make second important group of constituents of cereal grains. They occupy an average range of about 8–11% of the grain mass (Table 1). However, there are significant variations in the protein content. For example, soft wheat grains may vary from less than 6% to more than 20% (Souci et al., 2008). The results given in Table 1 show that most proteins contained durum grains 13.31 g 100 g^{-1}, followed by oat, barley and soft wheat in the range of 12.86–12.61 g 100 g^{-1} which is significantly lower compared to other studies. Polished rice is the poorest 7.07 g 100 g^{-1} and cannot be considered as an important source of protein, which is in agreement with the results of other studies (Šramkova et al., 2009).

The analysed samples in the same type of cereal show the highest differences among rye 3.35 (13.36–10.01 g 100 g^{-1}), and the smallest in barley 1.71 (13.28–11.57 g 100 g^{-1}), but

corresponded with investigations by Lexhaller et al. (2016) (Fig. 2). These results are somewhat lower compared to the reference values given by Luallen and Eliasson (2004) and Heshe et al. (2016). The content of proteins in these species compared to the content in millet, brown rice, polished rice and rye marked as important.

Difference	1.79	3.92	1.71	3.35	2.57	2.38	2.06	3.28

Figure 2. Differences between minimum and maximum value for grain protein content at commercial cultivars (n = 30)

Generally taken over these studies, fats are slightly represented in cereals (Newton et al., 2009), but play a great importance in the formation of inclusion complexes with proteins (Luallen and Eliasson, 2004) and with starch (Horstmann et al., 2017). Cereal lipids originate from membranes, organelles, and spherosomes and their content in the grains depend on cereal species and vary from 1.7–7% of the dry weight (Delcour and Hoseney, 2010). Except oats (~7%), cereal lipids belong to the minor constituents (2–4%) (Belitz et al., 2009). Crude fat is mostly contained in commercial oat grains 4.91 g 100 g^{-1} and this value is significantly higher compared to other cereals (Gujral, 2012). The lowest fat content was found in durum 1.84 g 100 g^{-1}, which coincides with carried out study (Kumar et al., 2011). Significant differences in fat content were also found by comparing polished rice (3.48) and rye (3.38) with all other cereal species (Table 1).

The largest differences between the maximum and the minimum value of fat were found in the millet samples 1.96 (3.98–2.02). The smallest fat content had polished rice 0.63 (3.68–3.05 g 100 g^{-1}) (Fig. 3).

Plant fibre has influenced the digestive micro flora as prebiotics serve for its nutrition and maintenance with the highest average content (Horstmann et al., 2017). The highest content of fibre is measured in oat grains 9.89 g 100 g^{-1} and at least at polished rice 0.40 g 100 g^{-1}, which is quite understandable if it is known that they are present in the grain coat layers (Sarawong et al., 2014) (Table 1). The crude fibre content in oat and rye grains was statistically significantly higher compared to all other species. Obtained results corresponded with literature data (Gebruers et al., 2008) for wheat and durum seeds. Analysis of laboratory samples showed the highest variation at rye 2.33 (10.65–8.55 g 100 g^{-1}), and the lowest in the polished rice 0.13 (0.47–0.34 g 100 g^{-1}) (Fig. 4).

max	2.98	3.44	6.35	8.77	10.65	3.98	3.65	0.47
min	2.78	2.53	4.65	6.44	8.55	2.22	2.69	0.34
Difference	0.20	0.91	1.70	2.33	2.10	1.76	0.96	0.13

Figure 4. Differences between minimum and maximum value for grain crude fibre content at commercial cultivars (n = 30)

	Soft wheat	Durum wheat	Barley	Rye
max	24.99	27.56	9.67	15.62
min	18.02	24.78	6.96	12.59
Difference	6.97	2.78	2.71	3.03

Figure 5. Differences between minimum and maximum value for grain wet gluten content at commercial cultivars (n = 30)

The gluten content is quite variable within each studied crop (Barada, 2010), and regarding dry gluten it generally corresponds with the results of so far researches (Bustamante et al., 2017), although our results are higher for wet gluten. The highest mean value for the content of the wet gluten at commercial cultivars was confirmed in durum 26.33 g 100 g^{-1}, while the lowest was in barley 8.19 g 100 g^{-1}. It is evident that highest variation was found among wheat samples 6.97 (24.99–18.02), and the lowest in barley 2.71 (9.67–6.96) (Table 1, Fig. 5). The differences in the content of wet gluten among all studied cereals were statistically significant.

	Soft wheat	Durum wheat	Barley	Rye
max	16.51	9.45	4.35	3.39
min	12.26	7.98	3.67	2.39
Difference	4.25	1.47	0.68	1.00

Figure 6. Differences between minimum and maximum value for grain dry gluten content at commercial cultivars (n = 30)

Unlike the oat which is gluten free cereal (Hegazy et al., 2009) wheat grains contain the highest average value of dry gluten 14.81 g 100 g^{-1} where are the largest variations between the individual laboratory samples 6.97 (16.51–12.26). The maximum measured value was found in wheat 16.51 g 100 g^{-1}, while an average the lowest in rye 3.03 g 100 g^{-1}. The rye contained minimum content in general measured 2.39, in contrast to the variations between analytical samples that are the smallest in barley 0.68 (4.35–3.67) (Table 1, Fig. 6).

Conclusions

Based on the results presented, it can be concluded:

The most proteins contain grains of durum commercial cultivars 13.31 g 100 g^{-1}, followed by rye and barley while polished rice is the poorest 7.07 g 100 g^{-1}. Durum protein content compared to the content in wheat, millet, brown rice, polished rice and rye showed significant differences.

Crude fat is mostly presented in oat grains 4.91 g 100 g^{-1} and this value is significantly higher than other cereals and the lowest fat contain durum grains 1.84 g 100 g^{-1}. Studied cereal grains concern fat are statistically significant different.

The highest content of fibre is recorded in oat 9.89 g 100 g^{-1} while at least at polished rice 0.40 g 100 g^{-1}. Fat content in oat and rye grains are significantly higher compared to other cereals. The content of the wet gluten component is the highest in durum 26.33 g 100 g^{-1}, while in the barley is the lowest 8.19 g 100 g^{-1}. Regarding the dry gluten, the highest value is found in wheat grains 14.81 g 100 g^{-1}, while in the rye is the lowest 3.03 g 100 g^{-1}. Differences in the gluten content the both wet and dry among all studied commercial cereal cultivars were statistically significant.

Cereals remain to be food for all the people of the planet although at some of them which are intolerant caused allergic based diseases and this study shown that with properly selection and combined with other non-cereal grains can be food worldwide.

Abstract

Pigeon pea (Cajanus cajan (L.) Millsp.) is the fifth most important food legume cropped in rain-fed agriculture in the semi-arid tropics of south Asia, Africa, and America Latin. It is used as source of proteins for food, feed add to the uses of wood in the fire and hedges. It grows in a wide range of edaphic and climatic conditions, making it well-suited to succeed in a variety of agricultural systems. Drought resistance of pigeon pea might be suitable in marginal land of Morocco in current climate change and might offer opportunities to diversifying protein's sources for both human and animals. Thus, seventeen genotypes received from ICRISAT germplasm were evaluated in different agro-ecological conditions of Morocco. The study aimed to analyze genetic variability, yield potential, yield components and grains and pods nutritional value using sixteen quantitative traits. Recorded data were used for descriptive and variance analysis and to build hierarchical cluster based on similarity and dissimilarity among genotypes. The results showed a high significant variability among genotypes for almost all measured quantitative traits. The genotypes AN33, AN34, AN21 and AN32 showed higher values for yield potential and grains nutritional value. Cluster analysis grouped the evaluated genotypes in four groups at 82% of similarity. The first cluster grouped the four previous performed genotypes, while the second and the fourth clusters grouped each one six genotypes. Whereas, the third cluster grouped a single genotype ATZ19 that was distinguished by late blooming, high pods weight, pods width, high number of seeds per plant and small seed size.

Keywords: *Pigeon pea, adaptability potential, yield and yield components, Morocco*.

Introduction

Pigeon pea (Cajanus cajan (L.) Millsp.), is one of the major pulse crops of the tropics and sub tropics (Vanaja et al., 2010). It belongs to Fabaceae (Leguminosae) family that provides sustainable farming system especially for marginal lands through their ability to improve soil texture and fertility. In addition, their grains may contribute to food and feed security thanks to their high nutritive value. Pigeon pea is a perennial crop with more diverse uses way than others grain legumes (Domoguen et al. 2010). Furthermore, Pigeon pea is a harsh crop that is adapted to a wide range of environments and cropping systems add to its high drought tolerance. It is mainly used as de-hulled split peas, as immature green seeds and pods are also consumed fresh as a green vegetable or as fodder. Regarding these specific characteristics, we have been encouraged to introduce and extend this crop to Moroccan farming system to take benefit from its high tolerance to water deficit and the high nutritional value of its seeds and pods. Thus, present research aimed to evaluate the adaptation potential of a collection of pigeon pea genotypes received from ICRISAT germplasm in different agro-ecological Moroccan environments.

Material and Methods

Plant material

Potential adaptation of seventeen genotypes of pigeon pea received from ICRISAT germplasm was evaluated under agro-ecological Moroccan environments (Table 1). Sixteen agro-morphological and nutritional quantitative traits were used on the base of "Descriptors pigeon pea manual CIRP" (1993) (Table 2). The agro-morphological traits were recorded on three plants per genotype, and three simples of pods per plant. The nutritional quality concerns crude fibers content that is determined by the Weende and Prosky method (1988), and crude protein content that is determined according to Kjeldahl method (ISO16634).

Table 1: List of studied pigeon pea genotypes

Table 2: List of measured quantitative traits

Quantitative traits	Abbreviation
1. Days of flowering	DF
2. Days of maturity	DMAT
3. Pod length (cm)	PdL
4. Pod width (cm)	Pdw
5. Weight pod (g)	WPd
6. Number of Pod per plant	NPd/PL
7. Number of seeds per pod	NSd/Pd
8. Number of seeds per plant	NSd/PL
9. Seed length (cm)	SdL
10. Seed width (cm)	Sdw
11. Seed yield per plant (g)	SdYield/PL
12. Weight of 1000 seed (g)	W-1000Sd
13. Seed Protein content (%DM)	SdCP
14. Pods Protein content (%DM)	PdCP
15. Fibers content of seeds (%DM)	SdCF
16. Fibers content of Pods (%DM)	PdCF

Data analysis

The measured quantitative data were subjected to descriptive and variance analysis (ANOVA). A hierarchical cluster was built on the base of similarity and dissimilarity among the studied pigeon pea genotypes.

Results and discussion

Quantitative traits variability

Descriptive analysis revealed a large quantitative traits variability among pigeon pea genotypes mainly for plant yield components characters such as number of seeds per plant (CV=117.6%), seed yield per plant (CV=111.4%), weight of pod per plant (CV=106.3%) and number of pod per plant (CV=103.9%) (Table 3). These results reveal a variable genotype potential adaptation in Moroccan growing season conditions. Indeed, the earliness was ranged from 89-163 days after sowing. Six of evaluated genotypes are earlier (AN21, ATZ29, AN32,

AN33, AN34 and AN90). Flowering date was significantly and negatively correlated with seed yield per plant (-0.517***), number of pod per plant (-0.546***), pods length (-0.314*), seeds per plant (-0.476**) and crude proteins content of pods (-0.650***). While, significant and positive correlation was revealed between earliness and seed size as seed length (0.724***) and seed width (0.630***). Plant production potential was evaluated on the base of number of pod per plant, number of seeds per plant, seed yield per plant and 1000 seeds weight. The mean plant yield potential was 51g varying from 3.0g (ELK48) to 187.5g (AN21). The most productive genotypes were AN21, AN32, AN33, AN34 and ATZ19. Plant seed yield potential except flowering date, was positively and significantly correlated with number of pods per plant (0.920***), weight of pod per plant (0.88***), pods length (0.513**), pods width (0.322*), number of seeds per plant (0.984***) and with pods crude proteins content (0.648***).

The nutritional quality of seeds and pods was evaluated on the base of crude proteins and crude fibers contents. The mean crude proteins content was 16.3%DM and 6.23%DM respectively of seeds and pods. Seeds proteins content varied from 12.6%DM (ATZ38) to 20.8%DM (ELK51). While, pods proteins content varied from 5.02%DM (ATZ19) to 9.06%DM (AN32). Crudes proteins were more concentrated in seeds than in pods. Seeds proteins content was negatively and significantly correlated with 1000-seeds weight (-0.375**) and positively with pods length (0.376**). Whereas, pods proteins content was positively correlated with number of pods per plant (0.636***), weight of pods per plant (0.492**), pods length (0.501**), number of seeds per plant (0.593***) and seeds yield per plant (0.648***). The mean content of crude fibers in seeds (4.50%DM) ranged from 4.09%DM (AN21) to 4.98%DM (AN90) without significant variation among genotypes. The mean content of crude fibers in pods (3.50%DM) ranged from 3.01%DM (AN21) to 4.47%DM (AN33) (Table 3).

Figure 1: Agro-morphological quantitative characters variability among seventeen genotypes of pigeon pea

Genotypes clustering

Cluster analysis grouped the evaluated genotypes of pigeon pea in four groups at 82% of similarity. The first cluster grouped four performed genotypes AN21, AN32, AN34, AN33 according to earliness, high plant pods, seed production potential, and seed nutritional quality. The second and the fourth clusters grouped each one six genotypes. Genotypes grouped in second cluster are characterized by a moderate earliness flowering (90 to 122 days), low potential of seed production per plant. While, cluster IV grouped the late flowering genotypes (168 days from sowing) with a low seed yield potential per plant and a high seeds value of crude proteins content. Whereas, the third one grouped a single genotype ATZ19 that was distinguished by late blooming (147 days from sowing), high pods weight, wide pods, high number of seeds per plant and small seed size (Fig. 2).

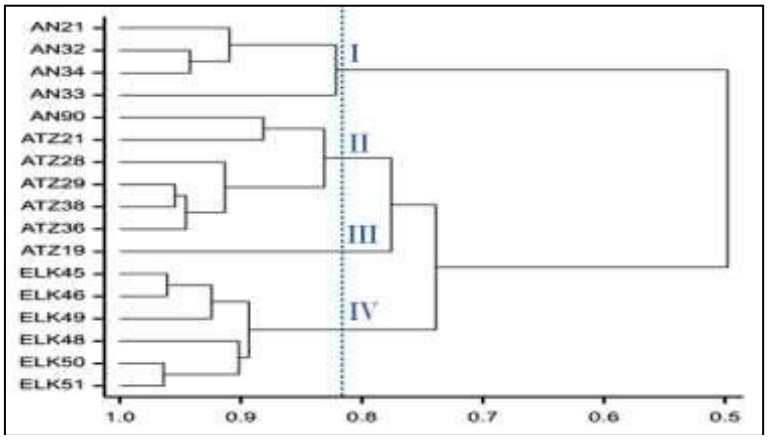

Figure 2: Clustering of seventeen pigeon pea genotypes based on seventeen quantitative traits

Conclusion

The introduction of Pigeon pea crop in the agro-ecological system of Morocco might be a good alternative in marginal lands. As leguminous crop, it may contribute to crop sustainability mainly in climate change context. Furthermore, Pigeon pea seeds contain high nutritive values mainly according to their high level of crude protein that may offer an important source of proteins for vulnerable people and also for animals.

The results showed a large genetic variability based on quantitative characters, from what six promising genotypes showed a high adaptation potential in different Moroccan environments according to their earliness, seed yield potential and nutritive quality. These promising genotypes might encourage research to develop improved varieties adapted to Morocco's edaphic and climatic conditions with both high productivity and nutritional value.

Abstract

Ornamental plants are important source of aesthetic value and the production of medicinal compounds. It is planted along the roads and parks due to its beautiful shape of pods and greenish look of leaves. Leaf and wood extracts of this tree has medicinal properties to control viral diseases. In this paper, we report an efficient protocol for somatic embryogenesis (SE) and plant regeneration of *Bignonia adenophylla*. Seeds were germinated *in vitro* on basic Murashige and Skooge (MS) medium to obtain green cotyledons from sterile seedlings and cultured on MS medium supplemented with thidiazuron or n^6-benzyladenine (BA) alone and with indol-3-acetic acid, α-naphthaleneacetic acid or 2, 4-Dichlorophenoxyacetic acid (2, 4-D) for callus induction. In the first experiment, greenish nodular calluses were grown on 0, 25, 50, 75 or 100% MS salts along with 0, 1.5, 3 or 6% sucrose for four days. In the second experiment, 0, 5, 10, 15 g/L silica gel powder was added in the plain agar for dehydration treatment. Highest (75%) callus induction was obtained with 0.139 g dry weight at BA (2 μM) + 2, 4-D (4 μM) after 36 days. Callus further proliferated and produced 80.33% somatic embryos, having 70.15 number of somatic embryos at 15 g/L silica gel after 15 days. Such somatic embryos germinated up to 11% into cotyledonary stage. We observed that TDZ inhibited the growth of shoot as well as root in the present study. Growth of such habituated cultures was further improved and produced somatic embryos on desiccation (silica gel) medium. The germination of somatic embryos was good enough that may further be improved.

Keywords: *Dehydration treatment, marud phali, somatic embryogenesis, sucrose, thidiazuron*

Introduction

Research curiosity on ornamental and medicinal plants is increasing day by day throughout the world to cater to the aesthetic aspiration and discovery of novel compounds for use in medicine. *Bignonia adenophylla* DC is one such tree that belongs to the family Bignoniaceae. This is a naturally-grown tree in India and other subtropical Southeast Asian regions for improving the aesthetic beauty of roads and parks due to its beautiful shape of pods and greenish look of leaves. In addition to this, leaf and wood extracts of this tree has medicinal properties to control viral diseases. It has been reported that the root extract has been used on snake bite (Jassbi *et al*., 2004). Generally, *B. adenophylla* is propagated through seeds in the field conditions. It produces limited number of viable seeds that might be due to unfavorable climatic conditions for fertilization. Moreover, conventional propagation methods for rooting of cuttings as well as bud sprouting in the nursery conditions are also very difficult. Limitations of conventional methods make this plant endangered in the plain areas of Pakistan. Somatic embryogenesis (SE) is very powerful tool of plant tissue culture for clonal propagation and the conservation of this plant. During SE, somatic cells undergo a series of morphological, physiological and biochemical events to develop into embryos on the tissue culture media containing suitable osmotica (Karami *et al*., 2006). Somatic cells pass through

different developmental phases of globular, torpedo and cotyledonary stages after extensive osmotic and desiccation treatments. Moreover, growth regulators and the amount of sugar in the medium also play role in inducing SE (Kubeš *et al.* 2014). Sucrose is a carbohydrate and being the main carbon source drives cellular metabolism for normal growth and development of *in vitro* plants (Karami *et al*., 2006; Kubeš *et al*., 2014). Optimum level of sucrose in MS medium is 3%, while its variable concentrations have been reported for somatic embryogenesis in different plant species (Yantcheva *et al.* 1998; Karami *et al.* 2006). Silica gel powder is a commonly used lab chemical for thin layer chromatography. This is also used as a desiccator and therefore absorbs moisture in different culture systems. Little information regarding the use of silica gel is available except for carrot somatic embryogenesis in an air tight box (Dumet *et al.* 1993). However, inclusion of silica gel into the culture medium for somatic embryogenesis has not been reported. Therefore, the objective of the present study was to explore conditions for somatic embryogenesis and maturation on various desiccation treatments using in vitro-germinating seedlings as an initial explant material of *B. adenophylla*.

Materials and Methods

Mature seeds of *B. adenophylla* were collected, surface sterilized with ethyl alcohol (65%) for few seconds and then decontaminated in 15% bleach solution (Robin, Reckitt & Colman, Pakistan) for 15 minutes and washed with autoclaved water under the laminar flow cabinet and cultured on MS (Murashige and Skooge, 1962) agar solidified medium added with 0.1% activated charcoal at pH 5.8 and autoclaved under the standard conditions (121 °C and 104 kPa). After inoculation, cultures were shifted to 16 h photoperiod at 25 ± 2 °C.

In vitro seedlings were used for the acquisition of the cotyledonary explants to grow them on MS medium supplemented with 2 µM TDZ (thidiazuron) or BA (N^6-benzyladenine) in combination with 1, 3 or 4 µM indol-3-acetic acid (IAA), α-naphthaleneacetic acid (NAA) or 2,4-dichlorophenoxyacetic acid (2,4-D). The rate of callus induction was calculated after 26 days. Fresh weight (FW) and dry weight (DW) of the calluses was determined.

Calluses pre-cultured on TDZ (2 µM) + 2, 4-D (4 µM) were used for somatic embryogenesis. For this purpose, 0, 25, 50, 75 or 100% MS medium + 0, 1.5, 3 or 6% sucrose were used for 15 days. Silica gel powder at 0, 5, 10 or 15 g/L in plain agar was also tested for somatic embryogenesis for 36 days. Embryogenic cultures were then shifted on to half MS medium with 3% sucrose for maturation. The developing embryos were germinated on MS medium with 3% sucrose.

Data analysis. One way ANOVA was used for mean values compared using DMRT. Simple regression analysis was also used for comparison of the data using SPSS v.16.

Results and Discussion

In the present study, callus induction was observed on all treatments from cotyledons. Fig. 1a and b show callus induction frequency as affected by different auxins in combination with cytokinins after 36 days of initial culture. The rate of callus induction was 44.23% that decreased subsequently with the increasing levels of NAA (Fig. A). This was followed by 2 µM 2, 4-D and 3 µM IAA with 43% and 43.32% callus induction, respectively. However, BAP was most effective when used with all levels of 2, 4-D followed by IAA, for callus induction with a highest (75%) callus induction response at 3 µM 2,4-D + 2 µM BAP after 36 days of initial culture (Fig. 1B). Explants showed different morphological changes on different treatments after 20 days of culture (Fig. 2). Explant on the basal medium did not show any change (no callus induction; Fig. 2A). Fast growth with white nodules were observed on the explant surface as well as from cut margins with 2, 4-D + TDZ (Fig. 2B). IAA was least supportive and resulted in little callus from cut surfaces (Fig. 2C). Within the

same period of time, NAA + TDZ produced brown calluses (Fig. 2D). Initially, the explants on 2, 4-D + BAP became necrotic (Fig. 2E) that subsequently invigorated and formed huge mass of cells. Explants on IAA + BAP or NAA + BAP abruptly developed translucent callus tissues (Fig. 2F, G).

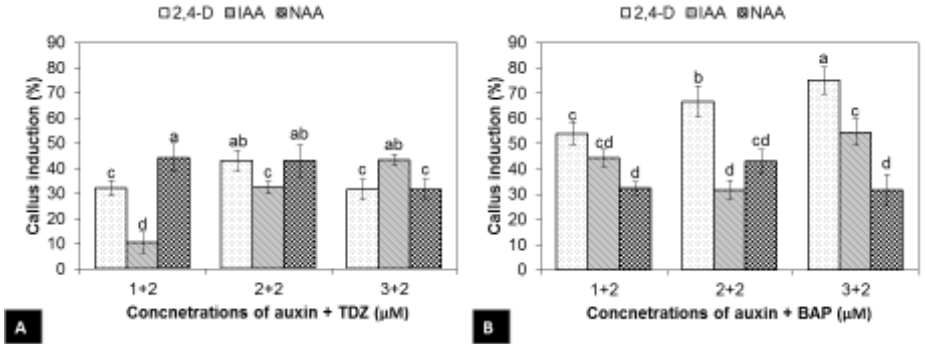

Fig. 1 Effect of different concentrations of auxins along with TDZ (A) or BAP (B) on callus induction in *B. adenophylla* from cotyledons after 36 days of culture.

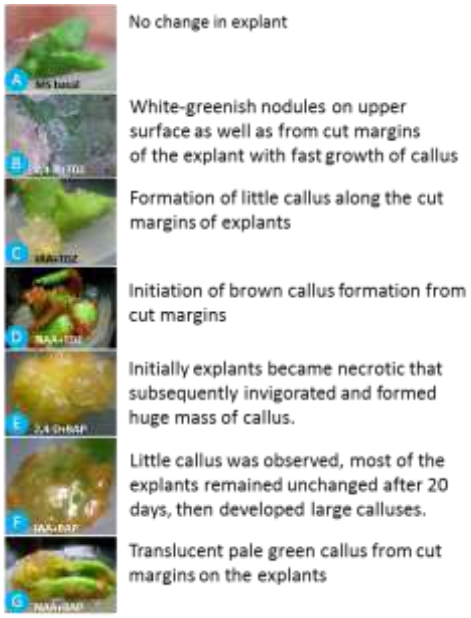

Fig. 2 Morphological characteristics of calluses induced on different treatments in *B. adenophylla* after 20 days of culture.

The highest (2.121 g) fresh weight (FW) of calluses was obtained at BA + IAA as compared to other treatments (Fig. 3). Similarly, the dry weight (DW) of such calluses was also highest (0.339 g) which was 15.98% of its fresh weight.

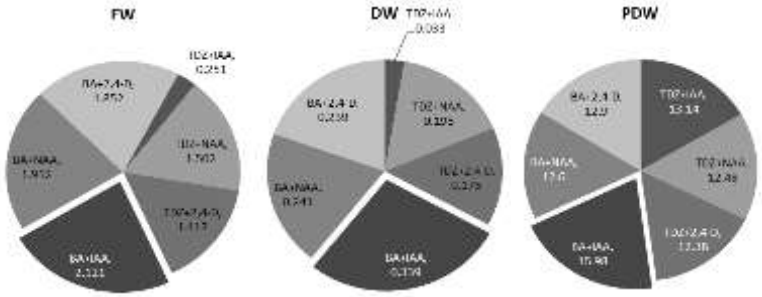

Fig. 3 Pie charts showing the effect of different treatments on fresh and dry weight of callus cultures of *B. adenophylla.* FW: Fresh weight, DW: Dry weight, PDW: Percent dry weight

Fig. 4 Callus induction and somatic embryogenesis from cotyledons of *B. adenophylla*. **A)** Callus formation on the surface of cotyledon at 2 µM BA + 3 µM 2, 4-D after 26 days. **B, C)** Green calluses (36 days old) formed embryo-like structures on the surface (arrows) on plain agar augmented with 15 g/L silica gel. **D, E, F, G)** Development of somatic embryos through globular, sickle, torpedo and cotyledonary stages observed on plain agar added with 15 g/L silica gel pre-cultured on TDZ (2 µM) and 2, 4-D (3 µM). **H)** Germination and further development of somatic embryo.

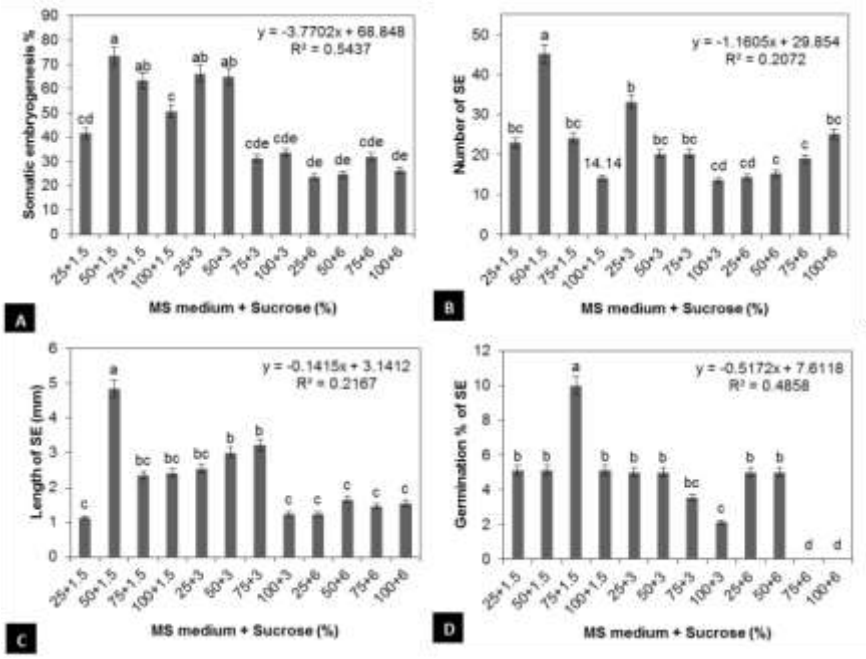

Fig. 5 Induction and further development of somatic embryos (SE) of *B. adenophylla* on various strengths of MS medium supplemented with different levels of sucrose (% values are given) after 36 days.

Callus appeared from cut explant margins (Fig. 4A), however, when transferred to the desiccation medium, it formed embryo like structures on its surface on plain agar medium + 15 g/L silica gel previously cultured on TDZ (2 µM) and NAA (3 µM) after 36 days (Fig. 4 B, C). Various shapes of somatic embryos (SE) were observed, for example, globular (Fig. 4D), sickle (Fig. 4E), torpedo (Fig. 4F) and cotyledonary stages (Fig. 4G) were observed on 3 µM 2, 4-D + 2 µM TDZ. The cotyledonary shaped SE were then germinated into shoots (Fig. 4 H).

Different concentrations of MS medium + sucrose (Fig. 5) as well as silica gel in MS basal medium (Fig. 6) formed and developed SEs. By increasing the levels of sucrose the somatic

embryogenesis was decreased. Sucrose at 1.5% + 50% MS medium formed 73.45% SE (Fig. 5A) with 45.21 numbers (Fig. 5B), 4.85 mm long (Fig. 5C) and 5.11% germination (Fig. 5D) was obtained. This was followed by 1.5% sucrose + 100% MS (63.33% SE, 24.21 number, 2.36 mm length and 10% germination). However, the embryos formed on these treatments were morphologically dissimilar and deprived. SEs were significantly improved by increasing the concentration of silica gel (Fig. 6). Highest (80.33%) somatic embryogenesis (Fig. 6A), 70.15 number (Fig. 6B), 6.16 mm length (Fig. 6C) and 11.01% germination (Fig. 6D) was achieved at 15% silica gel after 36 days of culture. SEs developed on silica gel were stout and vigorous.

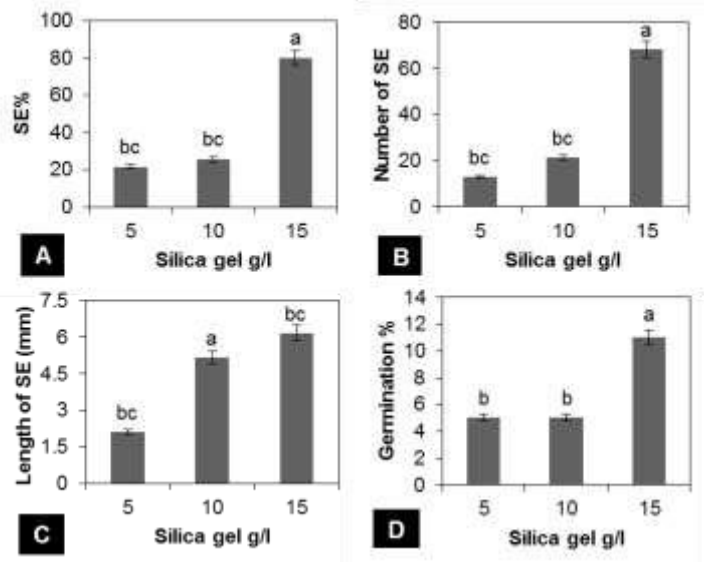

Fig. 6 Induction and further development of somatic embryos (SE) of *B. adenophylla* on different levels of silica gel in the medium after 36 days.

Regression analysis of the individual effect of sucrose, MS medium and silica gel were also compared (Table 1). High correlation (R^2 = 0.78) of somatic embryogenesis induction was observed by silica gel. This was followed by sucrose (R^2 = 0.55) and MS medium (R^2 = 0.06). Number of SE were highly correlated (R^2 = 0.803) by silica gel. The rate of SE germination was also significantly improved (R^2 = 0.72) by silica gel as compared to other desiccants.

Generally, somatic embryogenesis is achieved after passing through the cultured tissues on various chemical treatments, osmotic and desiccation stresses. Plant growth regulators (PGR) including cytokinins and auxins also play significant role in somatic embryogenesis. TDZ as a PGR kind of prepares the cultured plant cells to become somatic embryos physiologically by adjusting the optimum level of osmoticum (sucrose) in the medium (Martinez *et al.* 2008). Decreasing the moisture level in the culture medium is also known to push the plant cells towards somatic embryogenesis. For example, the use of 0.75 M sucrose supported the oil palm cells to become somatic embryos after the provision of desiccation with silica gel in the box (Dumet *et al.* 1993). Similarly, initial treatment of abscisic acid (ABA) induced somatic embryos on silica gel in cultured carrot cells (Ikeda *et al.* 2006). ABA in combination with silica gel improved the germination frequency of somatic embryos and survival rate by minimizing (up to 5%) the moisture level in the medium (Dumet *et al.* 1993). These reports support our findings of pretreatment effect.

In our study, TDZ pre-treatment followed by silica gel improved the growth and maturation of somatic embryos. Moreover, TDZ pre-treatment was more effective than BA when used along with auxins. Many other reports also confirmed the validity of our results working on different plants. Kumar *et al.* (2015) demonstrated that 0.5 mg/L TDZ + 20 mg/L picloram + 20 mg/L glutamine induced somatic embryos from calluses of *Pelargonium sidoides*. Chilling treatment improved the germination frequency after short exposure of calluses to TDZ of *Quercus robur* SE (Martinez *et al.* 2008). On the other hand, improved germination (61%) has been reported using BA (0.44 μM) + 0.29 μM gibberellic acid on MS basal medium (Vengadesan and Pijut 2009).

Conclusions

It was observed that TDZ inhibited the growth of shoot as well as root in the present study that may be due to its strong cytokinin activity (Huetteman and Preece 1993; Martinez *et al.* 2008; Akram and Aftab 2016). Such habituated cultures went to maturation and somatic embryogenesis on silica gel medium. The germination of somatic embryos was good enough that may further be improved under such culture conditions.

Abstract

Nowadays, farm tractors are characterized by high versatility – one tractor can be used at various works on different grounds. Different abilities of grounds can cause the differences in traction abilities of agricultural vehicles. In turn, it may make difficult to achieve the optimal pulling abilities of tractor; moreover, in some cases the high energy losses can occur. For this reason, the aim of provided research was to demonstrate the differences in values of selected tractive parameters (wheel slip, pulling force, traction force, tractive efficiency) on two surfaces with different properties. Research was conducted on cultivated soil with two compaction levels and on the pasture turf (with one compaction level). Two tires with similar external dimensions were used in experiment – the difference in this tires concerned their internal construction; 11.2R24 tire had a radial construction (higher flexibility), while 9.5-24 was the bias-ply tire with smaller flexibility. To measure the tractive parameters the measure device mounted o tractor was used. The measure parameters were: pulling force, torque of wheel with tested tire, rolling resistance, theoretical and actual velocities. Then, the values of wheel slip, traction force and tractive efficiency were calculated. Based on obtained results it can demonstrate that the radial tire had a less sensitivity to change of surface of exploitation – the differences in pulling force did not exceed 8% (for the tractive efficiency – 5%). For the bias-ply tire the higher values of pulling force were observed on the soil with higher compaction level (in comparison with the second soil the difference was equal 21%). Moreover, the bias-ply tire achieved the smaller tractive efficiency than radial tire – difference reached 11%. The comparison of the tires on the pasture turf allowed to show that both tires had similar values of pulling force, but the radial tire achieved the higher values of tractive efficiency.

Keywords: *agricultural vehicles, pulling abilities, tractive efficiency, compaction.*

Introduction

Agricultural vehicles, especially farm tractors, are used to different works. One tractor with the same tires can be operated on the grounds with extremely different properties.
It is also important that the variability of substrate conditions can cause differences in traction properties of agricultural vehicles.
Traction abilities are described by a few parameters such as pulling force (or drawbar force), traction force, wheel slip, tractive efficiency (Elwaleed et al. 2006, Zoz and Grisso 2003). From a practical point of view the important parameters are pulling force (it affects on pulling abilities of tractor) and tractive efficiency which describes the degree of recovery of power delivered to the wheels (indirectly it describes the energy losses in wheel-ground system).
The traction parameters are dependent on many factors which can be divide into two main groups:

- construction and maintenance factors: type of tires (radial, bias-ply), tires dimensions, type of a tire tread, vertical load, inflation pressure,

- factors related to the ground: compaction of the soil (am often it is described by the penetration resistance), shear stress strength, soil moisture, the plants coverage of the soil.

For many years, in literature the effects of research of wheel-ground system are presented. Researchers take into account both construction and ground factors. For example, Elwaleed et all (2006) describes the influence of tread high on traction abilities, in Smerda's and Cupera's research paper (2010) there are showed impact inflation pressure on traction performance. Gholkar et al (2009) focuses on simultaneous impact of vertical load and inflation pressure. Thaghavifar and Mardani (2013) presented comprehensive assessment of operational factors on traction properties.

Determination of influence of impact of ground parameters on traction abilities is a complex and difficult process. The main reason of this situation is the variability of ground parameters – on one filed there can be the places with different compaction levels. In the case of the cultivated soil, important factor is the cultivation system (Moitzi et al 2006, Arviddson 2010). Moreover, each change of actual humidity can result in changes in compaction. These factors can cause variability of traction properties of agricultural vehicles (Aday et al 2004, Gharibkhani et al 2012, Inchebron et al 2012). In literature there are showed papers described influence of ground parameters on traction abilities (Xu et al 1991, Lyasko 2010, Narang and Varschney 2006) but am often they concern specific condition and places – their "universal" use is limited. For this reason, it is reasonable to continue the research in this range. The aim of research was to determine the differences in traction properties of two agricultural tires operated on different grounds.

Material and Methods

The experiment based on measurements of tractive parameters for two agricultural tires (the parameters of these tires was shown in Table 1). During the tests the one level of inflation pressure (0,14 MPa) and vertical load (8060 N) were used.

Table 1. Parameters of tested tires

Tire	Construction	External diameter, mm	Width, mm	Rim diameter, mm	Tread high, mm
9.5-24	bias-ply	996	241	610	35
11.2R24	radial	1000	284	610	35

In experiment, the main factor influenced the traction properties was the type of the ground. Research was carried out on the three grounds: cultivated soil with low compaction, cultivated soil with high compaction and the pasture turf. The description of the grounds was shown in Table 2.

Table 2. Description of the grounds

Ground	Actual moisture, %	Compaction, MPa	Shear stress strength, kPa
Compacted soil	13,3	0,82	28,6
Loose soil	22,3	0,56	19,0
Pasture turf	20,7	1,24	66,2

To determinate the traction parameters the special measure stand was used. This stand was mounted on three-point linkage of a Massey-Fergusson 235 tractor. The base of stand was a two-piece frame. The tested wheels were mounted on the shaft which was driven from PTO

through the hydraulic-mechanical transmission. The measure stand was equipped in force sensor (measure accuracy 10 N in range 0-100 kN), torquemeter (accuracy 1 Nm, range 0-3000 Nm) and two rotational sensors for speeds measure. All measured parameters were sent to electronic recording connected with portable computer. Based on values of measured parameters (pulling force, torque, actual speed, and theoretical speed) other traction parameters were calculated, according to formulas 1-6.

$$\delta = 100 \cdot \left(1 - \frac{v_R}{v_T}\right), \quad (1)$$

$$P_T = \frac{M_O}{r}, \quad (2)$$

$$\eta = \frac{P_u}{P_T} \cdot (100 - \delta), \quad (3)$$

where:
δ – wheel slip, %,
v_R – actual speed, ms^{-1} (measured),
v_T – theoretical speed, ms^{-1} (measured),
P_T – traction force, N,
M_O – torque of wheel, Nm (measured),
r – wheel radius, m,
η – tractive efficiency, %,
P_u – pulling force, N (measured).

During the experiment the tested wheel was driven from PTO while the gearbox of tractor was in neutral position. When the measure stand with the tractor was moving, the traction parameters were measured and recorded. In the final part of measurement the tractor was smoothly stopped by brake, then the tested wheel was rolling with increasing slip (at the end the wheel slip was equal 100% and the wheel rotated without linear move). Each of measurements was done in 3 repetitions.

Results and Discussion

According to the aim of research the based traction parameters were determine. Figure 1 shows the values of pulling force, for both tires on three grounds.

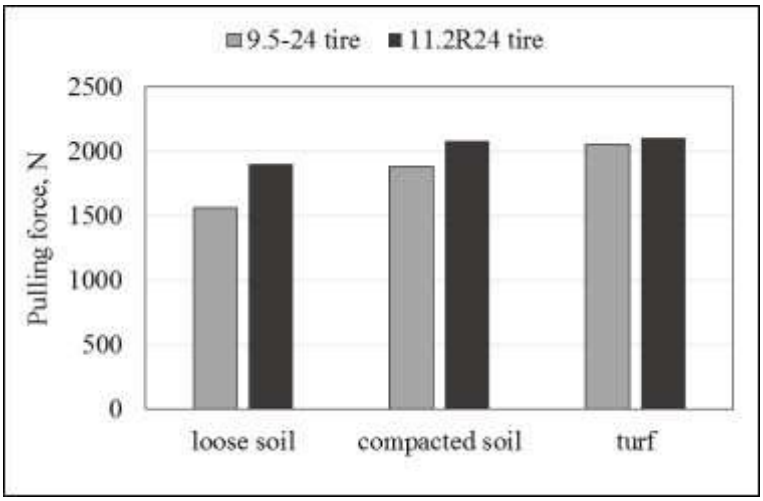

Fig. 1. The values of pulling force (arithmetical means calculated for slip range 0-30%)

In Figure 1 it is visible that the 11.2R24 tire obtained higher values of pulling force than the 9.5-24 tire. This trend was observed in any case of ground, while the highest difference

concerned loose soil (339 N, which is 21,6%). On the pasture turf the differences was the smallest (49 N, 2,3%). These differences can be caused by different construction of both tires. Radial tire (11.2R24) had a better flexibility and it can be better fitted to the ground. Probably, the contact area of radial tire was greater than in the case of bias-ply tire (it can reduce the wheel slip). The advantage of radial tire was shown by other researchers (Materek 2006, Botta et al 2008). It is also visible that the higher compaction causes increase in pulling force. This trend also refers to other research. The similar effects were obtained by Xu et al (1991), Jun et al (2004) and Narang and Varschney (2006).
The second analyzed parameter was the tractive efficiency. The maximum values of this parameter were presented in Figure 2.

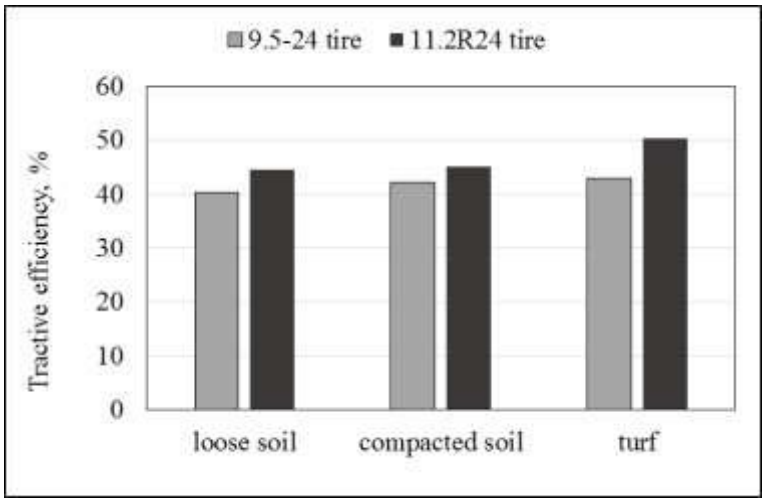

Fig. 2. The values of tractive efficiency (maximum values in the slip range 0-30%)

In accordance with Figure 2 the highest values of tractive efficiency (51,4%) was obtained by the wheel with the 11.2R24 tire on the turf. The lowest tractive efficiency (40,3%) was observed for the bias-ply tire (9.5-24) on the loose soil. The maximum absolute difference between the efficiency for both tires exceeded 11% (relative 27,5%) . For radial tire there is good visible dependence between ground parameters and tractive efficiency; higher compaction (and shear stress strength) allowed to obtain higher tractive efficiency. It refers to other research – Narang and Varschney (2006), Gholkar et al (2009), Wulfsohn and Way (2009) reported that higher soil strength can cause better traction properties. Moreover, it can be found that the bias-ply tire was less susceptible to change of ground parameters, but their traction properties were worse than for radial tire.

Conclusions

Based on obtained results, following conclusions were formulated:
1. The wheel fitted with radial tire obtained higher values of pulling force that wheel with bias-ply tire. The highest difference in pulling force between both tires was observed on loose soil, while lower difference was on the pasture turf.
2. Higher values of tractive efficiency were obtained by the wheel with the radial tire. This trend was observed on all three grounds, but the highest difference between both tires was observed on the pasture turf.
3. Higher strength of the ground (described higher values of compaction and shear stress strength) allowed to obtain better traction properties of both tested tires wherein bias-ply tire was less susceptible to change of ground parameters (for this tire the differences in tractive efficiency on different grounds were smaller than for radial tire).

MORPHOLOGICAL PROPERTIES OF DIRECTLY SOWED SWEET CORN PLANTS CULTIVATED WITH COVERING TECHNOLOGIES

Ferenc OROSZ

Sapientia University, Department of Horticulture, 540485 Targu Mureş, Şoseaua Sighişoarei 1C, Romania
*Corresponding author: oroszferenc67@gmail.com

Abstract

Aim of experiment set up in 2014 was, to study the evolution of sweet corn growing period with application of some technological elements: propagation time, propagation method, floating row cover. The choosen variety was a conventional, very early ripening sweet corn hybrid, 'Spirit'. The following growing technologies were compared: 1. direct sowing of plants with floating row cover, early period 2. direct sowing of plants without row cover, early period 3. direct sowing of plants with floating row cover, normal period and 4. direct sowing of plants without row cover, normal period (regarded as control).

It was studied the influence of above mentioned technological elements on some important morphological properties of sweet corn plant: evolution of phenological phases, plant height, tassels length, ear weight, height of ear insertion.

Key words: *earliness, sweet corn, vlies covering*.

Introduction

Based on its present growing area, the sweet corn is the vegetable which is grown on the greatest area in Hungary. After dates of Hungarian Fruit & Vegetable Interprofessional Organization in 2003 the maximal growing area was about 38,000 hectares. After 2003 followed a suddenly and sharp decline. After diminishing, the plant returned in rise, in 2006 against over 30,000 hectares. The recession mentioned above affected not only Hungary but also the holdings of the USA and Western Europe. In the case of the former, however, the increase in fresh consumption partly counterbalanced the rate of decrease. Near 50% of world sweet corn production came from US (Slezák *et al.*, 2012). In 2013 the growing area was 34, 000 hectares, less with 1000 ha, compared to 2012 (Avar, 2013).

In order to promote fresh consumption, as well as to maintain and increase the sweet corn exports, it is necessary to promote investigations so as to be able to ensure a further increase in the growing area and yields of sweet corn with the help of the experiences. The literature mainly is concerned with maize growing technology, but a lot of dates could be used by sweet corn. Some sweet corn varieties have much shorter vegetation period, in which they are very sensitive to the weather conditions, especially during germination and emergence as compared to the other subspecies of maize (Dolijanovic et al., 2014). Sowing date of sweet corn is one of the factors which influence both the ear yield and its quality (Rosa, 2014).

Ripening can occur earlier when sowing earlier and using high quality seeds as compared to normal or late sowing. I'só (1969) and Pásztor (1966), after their multi-year sowing date trial, concluded the following: in the case of an earlier sowing seed germination will be more protracted, but silking and harvesting occur sooner than by lately sowing time. After multi-year trial Berzsenyi et al. (1998) have studied the effect of different sowing times on maize development.

Several techniques are known in the art for the purpose of early fresh market shipments: seedling growing or direct seeding with temporary plant cover (Hodossi, 2004).

About the covered early sowing as a technological variation Aylswirth (1986) mentioned, that from an early sowed crop, made in first week of April, arranged in twin rows (42 cm) and covered by plastic, we could harvested marketable cobs by the fourth of July. In case of direct

sowing, as propagation method, another earliness increasing solution is the temporary covering with plastic or vlies, used in different combinations (Hodossi and Kovács, 1996).
Rattin et al., (2006) compared direct sowed and transplanted sweet corn varieties, without covering and concluded no difference, in ear weight and ear length, between transplanted treatments plant's, in comparison to direct sowing treatments plant's.

Materials and methods

The experiment was set up in 2014 on an area eqiupped for irrigation at Tg-Mures, Mures County, situated in Central part of Romania. Conventional, reliable and sufficiently known among growers sweet corn variety, Spirit, was used as a reference variety in the variety comparison trials of the Central Agricultural Office. Hybrid has short growing period of 85 days and yellow kernels. Average height of plants is 159 cm, average ear height is 37 cm, ear length 19.6 cm and average ear weight is 245 g. The variety was granted official recognitions in 1988 and has been the dominant variety of the early ripening category till now. In the year prior to the experiment the area was under wheat.
The following treatments, each with four replications, were applied during the experiment:
P1 = covered direct sowing (April 8th)
P2 = uncovered direct sowing (April 8th)
P3 = covered direct sowing (April 25th)
P4 = uncovered direct sowing (April 25th), (regarded as control).
For the frame structure of the treatments with cover we used ø 4.2 mm zinc coated wire coils. The fleece, 60 cm in width, was stretched over a small tunnel of 40 cm in height and then its edges (25-25 cm, respectively) were covered with soil using a hoe and the its ends were tied to the stakes hammered down. The construction of the frame structure and the setting out of the fleece cover were carried out at the same day as direct seeding and out planting.
At the two propagation times the treatments P1 and P3 were covered with Novagryl floating row cover, having a weight of 19 g/m^2, (using the small tunnel technique) in order to enhance earliness. The stand was created to contain 60,607 plants per hectare, according to the recommendations of the owner of the variety, at a spacing of 110+40x22 cm in twin rows. Each plot had an area of 6x3.5m (8 parallel rows and 16 seeds sown in each row). Sowing depth was 3 cm. The edge was the respective outer rows of the 4 twin rows of the plot.
In October 2013, 35 t/ha of farmyard manure was worked into the soil with ploughing on area. Nitrogen fertilizer (120 kg/ha) was applied at the 6-7 leaf stage, the form of top dressing. The fertilizer application was worked into the soil with a rotary hoe.
During the experiment, we studied plant growth rates and recorded the time of the occurrence of the major phenological stages. For this purpose, we carried out regular observations (every 3 to 5 days) according to the following:
beginning of seed emergence (appearance of first germs),
appearance of tassels (by 50% of the plants),
beginning of tasseling (pollen shed has begun on the axes of tassels),
50% silking (silks have reached a length of 2 cm on half of the ears) "milky stage" (harvest).
highness of plants (cm),
length of tassels (cm),
highness of ear insertion (cm).
Ears, together with the husks, were collected from the four central (two twin) rows and 20 ears of average appearance were selected from each row for following measurement:
unhusked and husked ear weight (gram).
The statistical analysis of the results was carried out by using the programme *RopStat 1.1*. When the standard deviations were identical the mean values were compared by pairs using the *Tukey-Kramer* test, while in the case of the non identical standard deviations the means were compared using the *Games-Howell* test (Vargha, 2007).

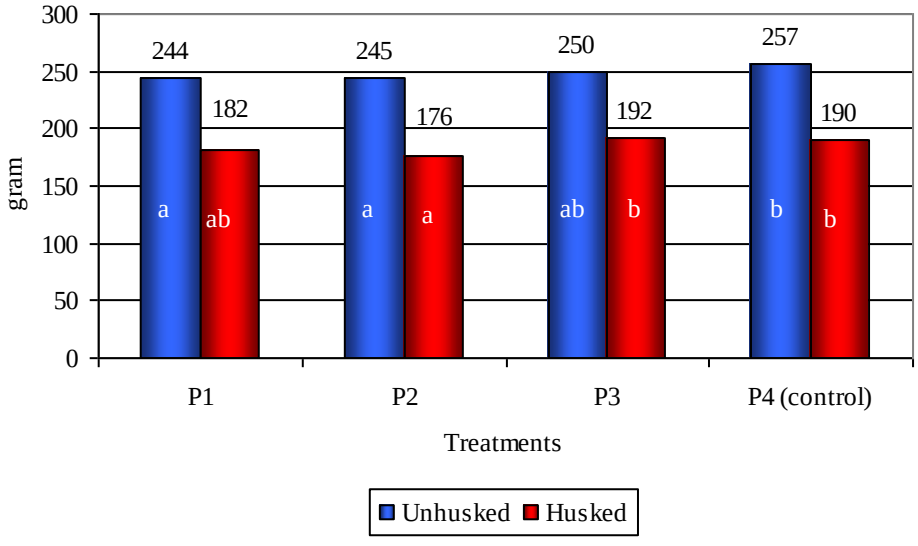
Results and discussion

Table 1. illustrates the times of sowing, emergence as well as the number of days elapsed from the date of direct seeding or transplanting to the different phaenological stages.

Table 1. Rhytm of emergence and generative phaenophases

Treatments (sowing day)	Date of emergence (days)	Tassels appearance by 50% (days)	Stigma appearance by 50% (days)	Starting harvest (days)
P1 (IV. 8)	15 (IV. 23.)	41 (V. 19.)	60 (VI. 7.)	76 (VI. 23.)
P2 (IV. 8)	17 (IV. 25.)	50 (V. 28.)	70 (VI. 17.)	85 (VII. 2.)
P3 (IV. 25)	9 (V. 4.)	52 (VI. 16.)	67 (VII. 1.)	83 (VII. 17.)
P4 (control) (IV. 25)	10 (V. 5.)	57 (VI. 21.)	71 (VII. 5.)	85 (VII. 19.)

It can be observed that time of germination in the treatment had sown at the first sowing date and having no cover had 2 days delay as compared to the germination time of the covered treatment and an significant (9 days) delay in beginning of harvesting time in 2014. Covering helped also in earlier appearance of generative phaenophases (tassels and stigma) by 9 days respectively, by 10 days earliness. In the case of the plants sown at the second sowing date the emergence could be considered practically normal as common. According to our results of experiment, the male flowers (tassels) appeared in the shortest time in the covered treatment. The covering, at this sowing time, resulted in 5 to 4 days earliness in appearance of generative phaenophases (tassels and stigma) compared to the P4 (control) treatment which had been direct sowed, uncovered at a similar time. Compared to the control (P4), the P3 treatment (covered) at the same date, could be harvested 2 days earlier. Earlier sowing time combined with plant covering (P1) treatment resulted, in 2014, an 24 days earliness compared to normal time sowed, covered (P3) treatment, respectively 26 day earlier harvesting compared to normal time sowed, uncovered (P4, control) treatment. Results of the one of the major characteristics in connection with yield rating, unhusked andhusked ear weight, are summarised in Figure 1.



F(4;174)=25,143; F(4;174)=11,836;Sd=99%

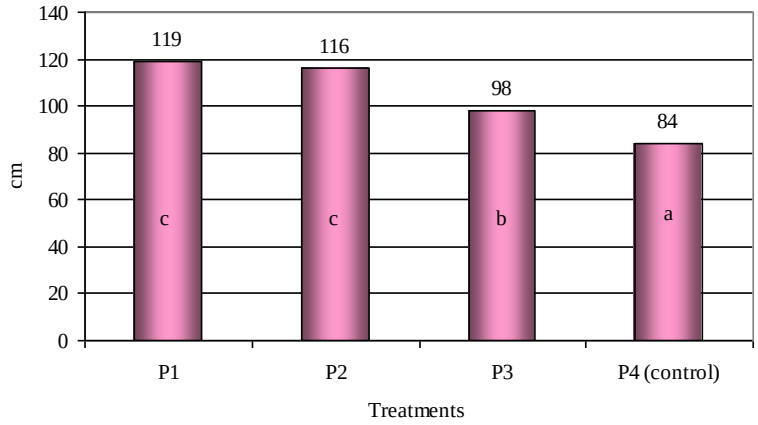
Fig. 1. Unhusked and husked ear weight (g).

Analysing the data measured for unhusked ear yield, it is noticeable that the average weight of

the ears of the normal time sowed, uncovered P4 (control) treatment was significantly (at *p<0.01* level) higher as compared to the earlier sowed, covered and uncovered treatments P1, P2. Though there was some difference between the unhusked ear weight of the normal time sowed, covered P3 treatment and in the same time sowed, uncovered P4 (control) treatment, which fact statistically was not significant.

In case of husked ear weight the normal time sowed, covered P3 treatment and in the same time sowed, uncovered P4 (control) treatment ear weight was significantly (at *p<0.01* level) higher as compared to the earlier sowed, uncovered treatment, P2.

The highness of plants indicator of general condition is represented by Figure 2.

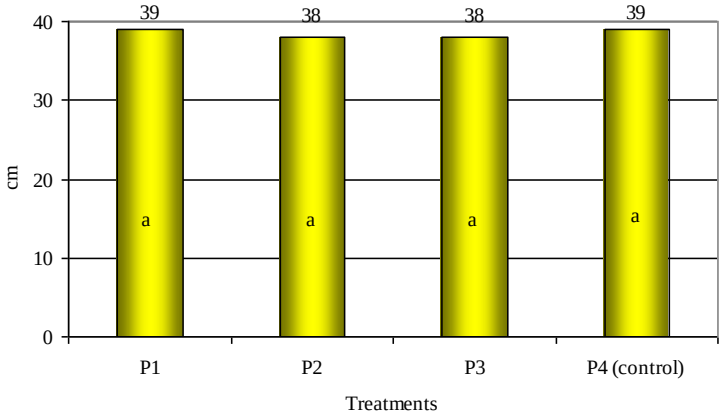


F(4;174)=14,240; Sd=99%

Fig. 2. Height of plants (cm).

The highest value of plant highness was registered by plants of earlier sowed (P1) covered and P2 earlier sowed (uncovered) treatments, difference was significantly (at p<0.01 level), compared to normal sowed (P3) covered and uncovered P4 (control) treatments. Covering (P1) had not favourable on plant highness compared to uncovered (P2) treatment by earlier sowing time.

Evolution of tassels length, supposed to carry more male flowers and implicite better pollination, is summarised on Figure 3.

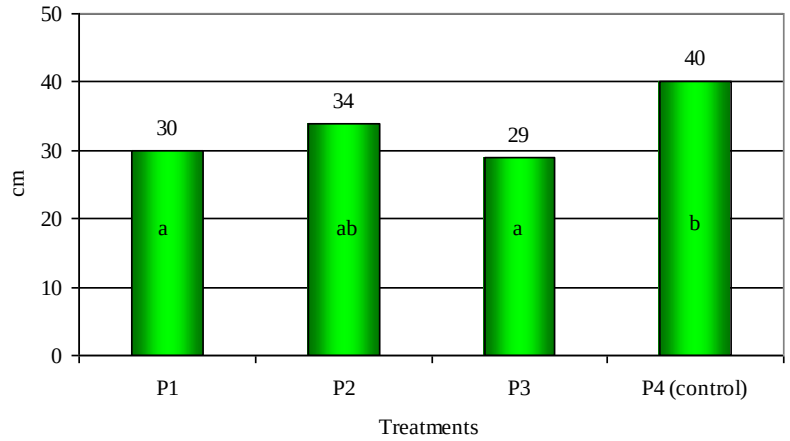


F(4;174)=17,42; Sd=99%

Fig. 3. Tassels length (cm).

In case of tassels length the time of earlier or later sowing and existence of covering had no significantly influence. Plants from earlier sowed, covered (P1) and normal time sowed

uncovered, control (P4) treatments had longer tassels compared to earlier sowed uncovered (P2) and normal time sowed covered (P3) treatments. Difference of tassels length statistically were not significant.
Highness of ear insertion is a very important morphological plant property in case of mechanical harvesting, because adapters of usual harvesting machines can cut only de sweet corn ears inserted higher than 40 cm, is illustrated on Figure 4.



F4;174)=3,481; Sd=99%

Fig. 4. Height of ear insertion (cm).

Obtained data confirmed significantly (at $p<0.01$ level) higher insertion of ears in case of earlier and later sowed, uncovered (P2 and P4) treatments compared to earlier and later sowed, covered (P1 and P3) treatments Covering on earlier sowed (P1) and normal time sowed P4 (control) treatments produced no favourable effect on highness of ear insertion. Mechanical harvesting in 2014 could not be used.

Conclusions

Based on the results of the 2014 year experiment, the following conclusions can be made:
In case to compare the earlier sowed P1 and P2 treatments, covering had 2 days earliness on date of emergence, shortened with 9, respectively 10 days, appearance of generative organs (tassels and stigmina) and shortened harvesting time at least with 9 days between earlier sowed (P1, P2) treatments and shortened harvesting time at least with 2 days between normal time sowed (P3, P4) treatments.
The growing period was significantly shortened with sowing time. Harvest time occurred 17 days earlier in the case of earlier sowed uncovered P2 treatment compared to direct sowed, uncovered, control (P4) treatment.
At the same time the floating plant cover combined with earlier sowing time produce 24 days shortening in the growing season between P1 (earlier sowing of plants with floating row cover) and P4 (normal time sowing of plants with no plant cover) control treatments.
In case of earlier sowed treatment (P1) the effect of covering had positive effect on unhusked, husked ear weight, hight of plants and length of tassels compared to P2 treatment.
In case of normal time sowed treatment (P3) the effect of covering had no important influence among measured morphological properties compared to P4 (control) treatment.
Covering had no significantly positive effect on height of ear insertion.
Mechanical harvesting in 2014 could not be used.

COMPETITION ON RAPE SEED MARKET IS GETTING STRONGER

Sergey GONCHAROV[1]*, Lyudmila GORLOVA[2]

[1] Crop Breeding Chair, Faculty of Agronomy, Agrochemistry and Agroecology, Voronezh State Agrarian University after Emperor Peter the Grate, Voronezh, Russia

Abstract

The article goal is to identify factors with higher input to the expansion of foreign seeds at the Russian rape seed market. Methods combined economic-statistical, abstract-logical, graphical, expert rating ones. Materials of the State statistics, the National Seed Registers, Russian Ministry of Agriculture, and USDA are used. Oil seeds acreage increased in this country +207% from 4 in 1990 till 12.3 m Ha in 2017 vs majority of cereals and fodder crops to be reduced. While spring rape seed acreage grew up fivefold, winter rapeseed has done fourfold during last 27 years, and is close to 1 m Ha. Farmers switch from cereals cultivation to oilseeds and, in particular, rape seed due to their higher margin, and oil seed processor demand. All-Russia Research Institute of Rapeseed, All-Russia Research Institute of Oil Crops by V.S. Pustovoit and Fodder Crops Institute are leaders on the local rape seed market. Number of listed local rapeseed varieties grown up +44%, from 48 in 2011 till 69 ones in 2017; and non-resident ones did +83% from 89 to 163 varieties for the last 7 years only. Foreign seed companies prefer to commercialize hybrids vs conventional varieties due to their more efficient return of investment to the breeding programs. Rape seed life cycle is assessed as 11 years for winter type varieties, and 13 years for spring ones. Hybrids market share is counted as 56% of spring, and as 76% of winter rape acreage. German seed companies (NPZ-Lembke, Bayer CS, and Deutsche Saatveredelung AG), American ones (Monsanto and Pioneer) and French ones (Euralis semences S.A., and others) domain on local markets. Clearfield and Express production systems (systemic herbicides application in combination with resistant hybrid varieties), improved fatty acid composition, and yellow color of seeds varieties may have competitive advantages.

Key words: *Rape, seeds, hybrid, conventional variety, seed market, breeding program*

Introduction

Oil crop acreage has been growing up at least for the last 25 years due to vegetable oil demand growth related with human prosperity. Even cereals are still main source of food calories for most of people, but they meet competition from oil crops in acreages, yields, productions, and margins. Rape is the second important oil crop worldwide with 36.4 million ha acreage, and 71.9 m tons production in 2017, which is less vs soya beans only (126,1 m ha and 347.9 m tons correspondingly). But it is superior vs sunflower (25,8 m ha, and 46.3 m tons). The article aim was to define some reasons and factors of loosing national seed market share by local breeders.

Materials and methods

The paper based on applied Economic-statistical, abstract-logical, graphical, expert ratings, regression methods, end expert assumptions. Materials of the National statistics, Ministry of Agriculture (www.mcx.ru), and USDA were used. The National Russian Registers of 2017 was analyzed (www.gossort.com).

Results and Discussions

Current commodity market challengers are favorable for growth of oil crop production in Russia (Fig. 1). Export logistic capacities were close to their limits within 2016-2017, but did not solve the problem of carryover stocks, as a result of cereal grain overproduction. State interventions (grain purchases) and subsidies also did not have a significant impact on market conditions. Low grain prices reduced of small grain crop production margin, as a result of which the agricultural producers increasingly began to consider oilseeds as an alternative crop to cereals. Finally, competition of oilseeds and cereals in the country is growing up.

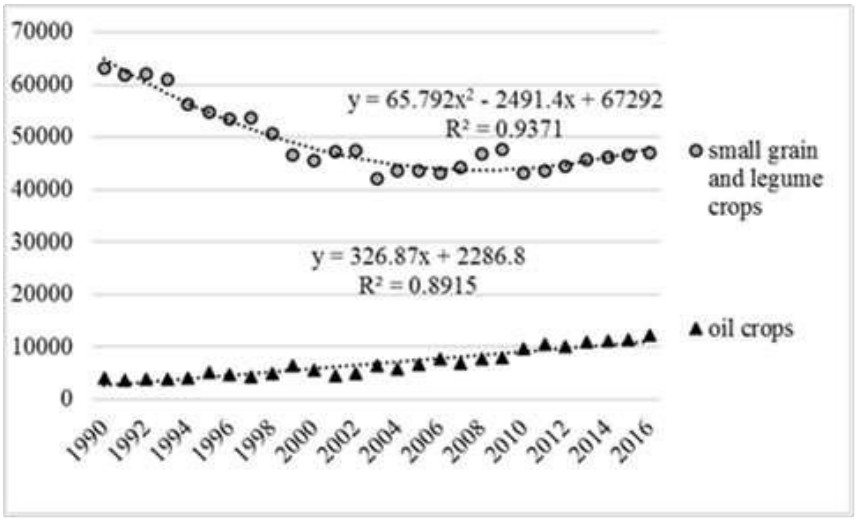

Fig.1. Dynamics of oilseeds, cereals and legume crops acreage in Russia, 000 ha, 1990-2017

Oilseeds (sunflower, soybean and rape) acreage simultaneously increased from 4.0 m ha in 1960 till 12.3 m ha in 2017, i.e. 0.25% on average per annum together with oil extraction plant consolidation and oilseed processing capacity growth in Russia till 24 million tons per annum. Sunflower acreage showed the largest growth dynamics in the Russian Federation, it was planted on 7.6 million hectares (+277% in 2017 vs 1990). Farmer choice in favor of soybean was realized in 330 % acreage growth, and nowadays it is more, then 2.2 m ha. There was a fivefold increase of spring rape planted area, and more than four times of winter rape during last 20 years (Fig. 2).

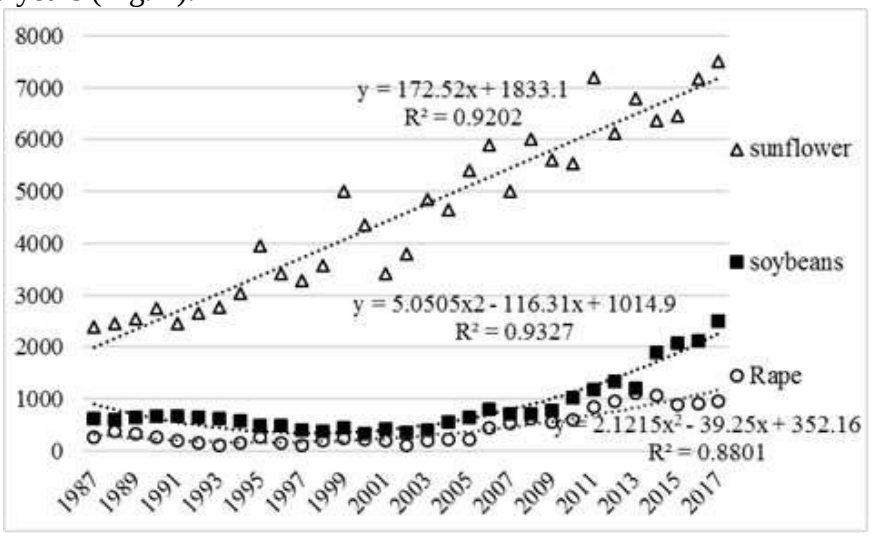

Fig. 2. Harvested acreage of main oil crops in Russia, 000 ha

Russia competes with the United State of America for the 6th place in the ranking of the world top rape seed producers, whose leaders are Canada, India, China and European Union. Russian farmers prefer to cultivate rape especially in traditional commodity areas of oilseed processing plants, and in livestock farms, which need reliable supply of oil meal and oil cake.
The acreage increase of oil crops and, in particular, rape, has required a proportional expansion of the assortment and enlarge of seed production volumes. There were 137 listed in the National register of the Russian Federation rape varieties in 2011, and 65% out of them were applied on behalf of 17 non-resident seed companies. There was a doubling of the listed assortment by 2017 with 232 listed entries, 72% out of them were from 24 foreign applicant. While national breeders increased the number of listed entries from 48 varieties in 2011 to 69 in 2017 (+44 %), the foreign ones did from 89 to 163 (+83 %). External applicants have abandoned conventional varieties in favor of hybrids. As a result, the share of hybrids in the National register is up till 57 % by 2017. Judging by the number of newly listed entries by 2017, such countries as Germany, the USA and France are the leaders in efficiency of rape breeding programs (Fig. 3).

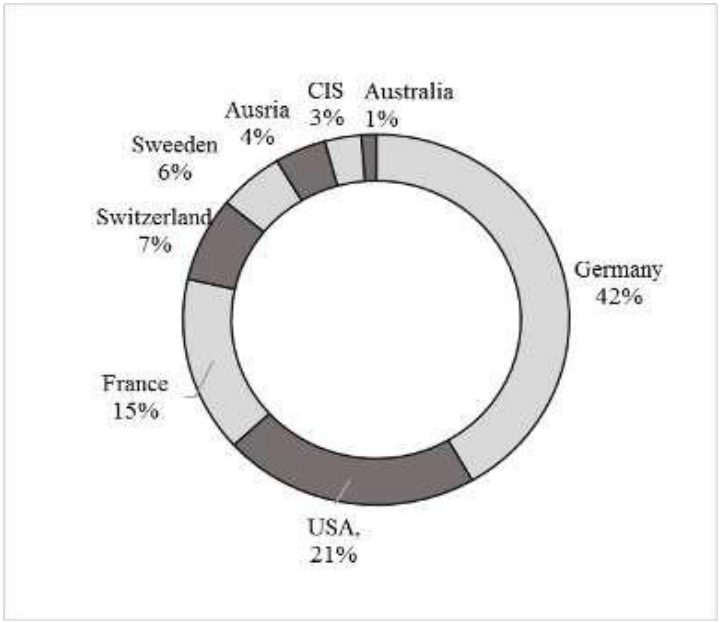

Fig. 3. Shares of listed rape entries from foreign countries, %, 2017

As for winter rape acreage, the share planted with foreign hybrids, has a significant tendency to decrease due to the improvement of local breeding programs, seed production development, as well as due to lower seed prices (Fig. 4).
However, with regard to spring rape, as well as to sunflower, the expansion of foreign genetics trend has not been overcome yet. Even in case of the sunflower hybrid multiplication by foreign seed companies is increasingly organized locally, non-resident rape seeds mainly imported. Rape seeds are multiplied and cleaned in most favorite zones for seed production. Non-resident rape seed share is estimated at 56% of spring rape acreage, 76% of winter rape, 74% of sunflower, and 26% of soybean by 2017.
Rape cultivated areas extension is accomplished with an improvement of seed product range offered in the market by breeding programs, only if the return of investment to breeding is efficient (Fedotov, Goncharov and Savenkov, 2008). Therefore, an expanded seed reproduction takes place. Western seed companies invest in hybrid breeding, but not in conventional varieties. German NPZ-Lembke domains on CIS rape seed market with market share about 40% in Ukraine, and slightly less in Russia.

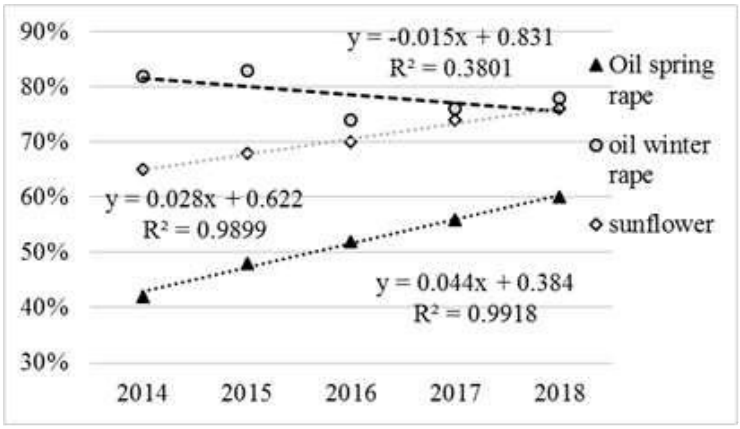

Fig. 4. Market shares of non-resident oil seeds in Russia, %

Other important non-resident players at the rape seed market are Monsanto, Pioneer, Bayer CS (that is currently completing the transaction for Monsanto acquisition), KWS, Deutsche Saatveredelung AG, Euralis semences, and others (Fig. 5). The growth of rape cultivated areas is accompanied with increase in the range of products offered to the market by breeders only in case of proper return of investment.

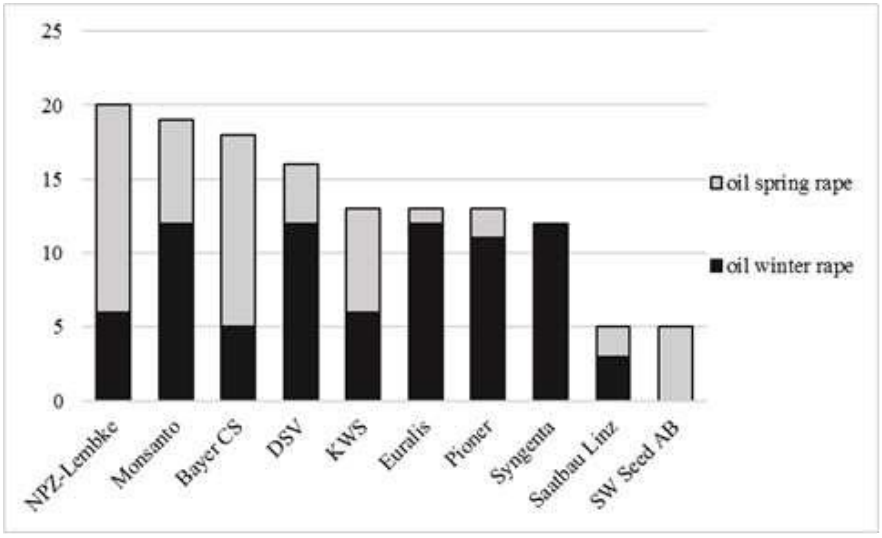

Figure 5. Top 10 foreign breeding companies, by the number of listed entries, %

The stronger competition in the seed market is evidenced by mergers and acquisitions of small seed market players by bigger ones. For example, rape breeding program of Raps GbR was purchased by Bayer CS; nowadays it is in process of selling to BASF. Rape breeding programs of German Saatzucht Diekmann GmbH & CO.KG and Polish Hodowla Roslin Strzelce SP Z O. O both were purchased by Monsanto. Syngenta also has changed the ownership from private shareholders to Chinese ChemChina State corporation.

Domestic Research and Development (R&D) organizations, which are mainly public Scientific Institutions, are funded from budgetary and non-budgetary sources in the ratio close to 50 : 50. In common they were not able to respond properly to market challenges due to their limited resources. Perhaps, it is one of the reasons for long seed life cycle, which is as 13 and 11 years for spring oil rape and winter oil rape. The threefold increase in the acreage of oilseeds after 1990 was not accompanied with a proportional expansion of breeding

programs, with range of varieties and hybrids, and with seed offer. Local All-Russia Research Institute of Oil Crops (Krasnodar), Rapeseed Institute (Lipetsk), and Institute of Feed Crops (Moscow region) have got the biggest market share registered (Fig.5).

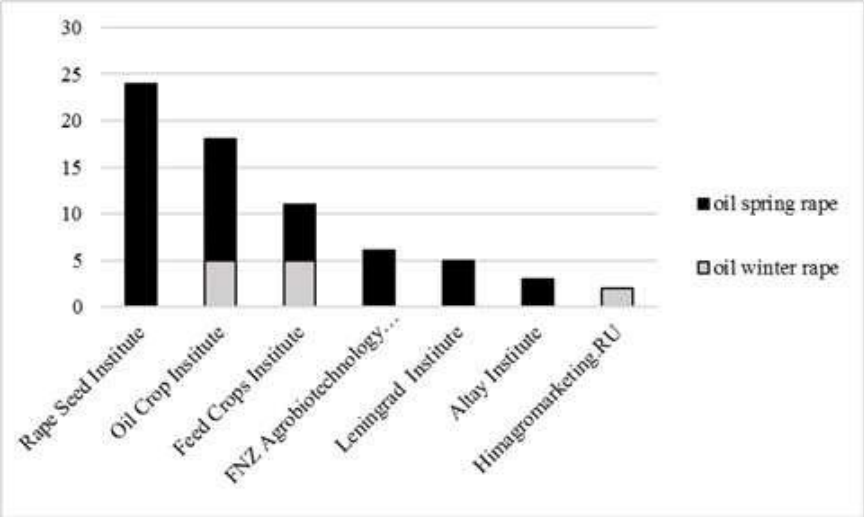

Fig. 5. Ranking of domestic breeding programs by the numbers of listed rape entries, 2017

However, due to geographic localization of rapeseed production in specific climatic zones, breeders tend to focus on breeding only spring or winter oil rape varieties (Goncharov and Gorlova, 2018). It is obvious that it is hard for domestic R&D organizations to compete with foreign seed companies, especially in the context of limited budget funding.

Such rape products with higher adding value are commercialized in this country, as CMS-hybrids, varieties with improved ratio of fatty acids (HOLL – High Oleic Low Linolenic, an oil with a high content of oleic, >70 %, and a low content of linoleic acids, <3%), oil resistance to oxidation during its shelve storage, yellow colored seeds etc. (Gorlova and Gorlov 2016; Gorlova and Bochkareva, 2017). IMI-technology (Clearfield herbicide *imidazoline* groups) in combination with resistant rape hybrids are implemented by farmers too.

Conclusion

There is strong market demand of oilseed commodity and, in particular, rape seeds in this country. Foreign seed companies (NPZ-Lembke, Monsanto, Limagrain, KWS, etc.) expand their activities in the rape seed market in Russia with support of their business models. Unsatisfactory return of investment to local breeding programs has the biggest input to their market share lost.

Abstract

Artichoke leaf is an important medicinal raw material because it produces preparations that influence blood detoxification and improves blood counts, affect the bile and liver, lower blood cholesterol, and enhance immunity to people after long-term treatment of chronic diseases. In the artichoke plant there are: essential oil, cinarin, glycosides and flavonoids. This plant is rich in fat oils, proteins, minerals and vitamins (A, C and B - complexes). The subject of the research was 4 genotypes: Institutska, Green Globe, Violet and Cardoon. The Experiment was set up at two sites, "Radmilovac" which is an experimental field Faculty of Agriculture of the University of Belgrade (Serbia) and private estate in Batkuša village (Bosnia and Herzegovina, Entity of Republic of Srpska, municipality of Šamac). The density of crops within the plots was different: 70 cm x 10 cm, 70 cm x 20 cm, 70 cm x 30 cm and 70 cm x 40 cm. The plot was set according to the Latin square system (random block system) and three factors were examined: genotype, density of crops and localities for yield of artichoke. The following values were measured: the rosette diameter, the number of leaves in the rosette, the largest leaf area, the weight of the dry plant and the dry leaf randman. Experimental plots at both sites were set at the beginning of April 2017. The results of the first year of the experiment showed that different sites did not significantly affect the tested parameters. The density of crops statistically significantly influenced the differences between the parameters tested. The variety Cardoon proved to be the most relevant, then the variety Institutska, while the worst results were shown by Violet.

Keywords: *Variety, genotype, site, crop density, yield.*

Introduction

Cynara scolymus L. (artichoke) is an ancient herbaceous plant, originating from the Mediterranean area, which today is widely cultivated all over the world. Its flower head is eaten as a vegetable and prepared for different value-added products such as salad, jam, concentrate, and canned beverages. Artichoke was first transplanted in China during the 1990s from Italy and Spain. In China, artichoke can be used for alternative products such as tea and alcoholic beverages. Its leaves have been used for hepatoprotection and as a choleretic and diuretic in traditional European medicine since Roman times (Kirchhoff et al., 1994). In Germany, it is used today as a choleretic (Kraft, 1997) for its lipid-lowering, hepatostimulating, and appetite-stimulating actions. Cynara was a relatively small genus, originating from the Mediterranean area that included two crops, globe artichoke (*Cynara cardunculus* var. *scolymus* L.) and cardoon (*Cynara cardunculus* var. *altilis* DC), as well as their ancestor, wild cardoon (*Cynara cardunculus* var. *sylvestris* L.) as demonstrated (Foti et al., 1999; Portis et al., 2005; Ierna et al., 2010). The earliest description of the Cynara came from the 4th century BC Greek writer Theophrastus. These plants were popular with Greeks and Romans as food and in medicine (Sonnante, 2007; Lattanzio, 2009). Artichoke played an important role in human nutrition, especially in the Mediterranean area (Lattanzio et al., 2009). Furthermore, it contributed significantly to the Mediterranean agricultural economy, where more than 60% of the total world production came from Italy which was classified as

the leading producer (about 474.000 t annually) followed by Spain (215.000 t), France (55.000 t) and Greece (25.000 t) (Ierna et al., 2010). Nowadays, the artichoke is cultivated in many parts of the world, such as the United States, mainly in California, in South America (Argentina, Chile, Peru), North Africa, Near East Turkey and Iran and China (Ierna et al., 2010; Lattanzio et al., 2009; Ceccarelli et al., 2007; Pandino et al. 2011).
Artichoke's commercial production is mainly based on perennial cultivation of vegetatively propagate clones (Lattanzio et al., 2009). The artichoke crop might last six or more years, reaching the maximum productivity in the third year (Ceccarelli et al. 2007).
This plant is genetically robust with a marked tolerance to pathogens. This is due to sesquiterpenes, cynaropicrin, which have antifeedant activities. (Ceccarelli et al. 2007).

Material and Methods

Experiment was set up at two locations, from the Faculty of Agriculture "Radmilovac" and on a private estate in the village of Batkuša (Bosnia and Herzegovina, Republika Srpska, the municipality of Šamac). The density of crop within the plots was different: 70 cm x 10 cm; 70 cm x 20 cm, 70 cm x 30 cm and 70 cm x 40 cm. The dimensions of one trial are 16.5 m x 21 m. Each of the parcels had sixteen plots of dimensions 2.8 m x 4 m. The distance between each of the plots was 1 m. The plot was set according to the Latin square system and three factors were examined: genotypes (Institutska, Green Globe, Violet and Cardoon), density of crops and localities for yield of artichoke. The following values were measured: the rosette diameter, the number of leaves in the rosette, the largest leaf area, the weight of the dry plant and the dry leaf randman by separating leaf nerves from the whole leaf, and then measured on balance scale. Experiment at both sites was set at the beginning of April 2017. The first harvest from both sites was done in the first half of July 2017. The results of the research were established by the method of variance analysis, and the significance of using the Fisher LSD test. The results are presented with graphs and tables.

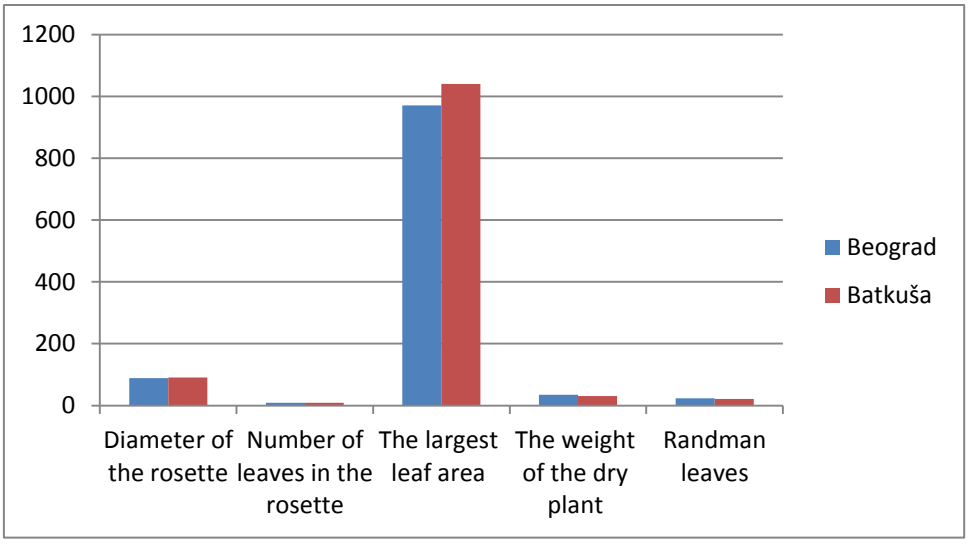
Results and Discussion

The first factor of this study is the location, the first location is Beograd and second is Batkuša. (Table 1, Graph 1). The dry parameter of the dry plant showed a statistically significant difference between Beograd and Batkuša. Better results were achieved in the location Beograd (34,369 g dry weight) than in Batkuša (30,726 g dry weight). Other parameters did not show statistically significant differences among localities.

Table 1. Results of examined parameters at different locations

Location	Diameter of the rosette (cm)	Number of leaves in the rosette	The largest leaf area (cm^2)	The weight of the dry plant (g)	Randman leaves (g)
Beograd	88,45	9,125	970,65	34,369	23,646
Batkuša	90,35	9,375	1040,40	30,726	21,496
LSD test	ns	ns	ns	*	ns

F test – LSD significance difference test; ns – not significant; * - significant; ** - very significant differences



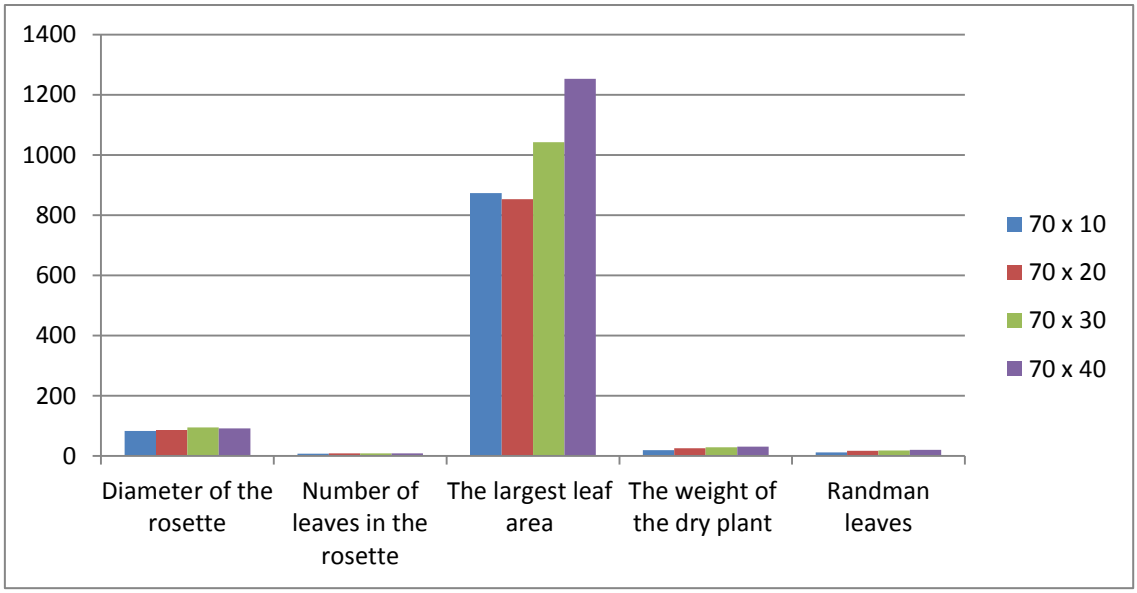
Graph. 1. Graphical presentation of the results of the tested parameters at different locations

Crop density is the second factor in this experiment (Table 2). The differences between the parameters tested were shown to be highly statistically significant. The diameter of the rosette was the largest in plants at a distance of 70 cm x 30 cm (on average 95.525 cm), while the smallest diameter of the rosette had plants that were at a distance of 70 x 10 cm (on average 83.225 cm). The number of leaves in the rosette was lower in plants in the densest assemblage (7.9), while this number was the highest in plants at a distance of 70 cm x 30 cm (9.225). The largest leaf surface in rosette was in plants at a distance of 70 x 40 cm (1252.7 cm^2), while the smallest leaf surface had plants at a distance of 70 x 20 cm (853.03 cm^2). The mass of the dry plant was the highest in plants with the greatest distance (31,371 g), while the smallest mass of dry plants was recorded in plants with the lowest spacing (19,664 g). Randman leaves were the highest in plants with the greatest distance (20,658), while the weakest randman was in the densest plant (12,407).

Table 2. Results of examined parameters in relation to different sowing density

Sowing density	Diameter of the rosette (cm)	Number of leaves in the rosette	The largest leaf area (cm^2)	The weight of the dry plant (g)	Randman leaves (g)
70 x 10	83,225	7,900	873,660	19,664	12,407
70 x 20	86,675	8,800	853,030	25,542	17,353
70 x 30	95,525	9,225	1042,800	29,614	19,006
70 x 40	92,175	9,075	1252,700	31,371	20,658
LSD test	**	**	**	**	**

F test – LSD significance difference test; ns – not significant; * - significant; ** - very significant differences



Graph 2. Tested parameters at different sowing density

The genotypes showed highly statistically significant differences in all parameters except for the largest leaf area in the rosette, where the differences are statistically significant (Table 3). The largest diameter of the rosette had a the variety Cardoon (107.15 cm) and the smallest the variety Green Globe (75.4 cm). The largest number of leaves had the Institutska (9,475) variety and the smallest variety Violet (8 sheets). The largest leaf area in the rosette was on average the highest in the tested plants of Cardoon (1074.3 cm^2) and the smallest in the Violet variety (917.49 cm^2). On average, the weight of the dry plant was the highest for Cardoon (33.758 g) and the lowest for Violet (20.725 g). Randman was in the highest ratio with Cardoon (22,207) and the weakest at Violet (14,467 g).

Table 3. Results of examined parameters in relation to different genotypes of artichoke

Genotip	Diameter of the rosette (cm)	Number of leaves in the rosette	The largest leaf area (cm^2)	The weight of the dry plant (g)	Randman leaves (g)
Institutska	98,20	9,475	988,89	26,864	16,036
Green Globe	75,40	8,325	1041,50	24,843	16,714
Violet	76,70	8,000	917,49	20,725	14,467
Cardoon	107,15	9,200	1074,30	33,758	22,207

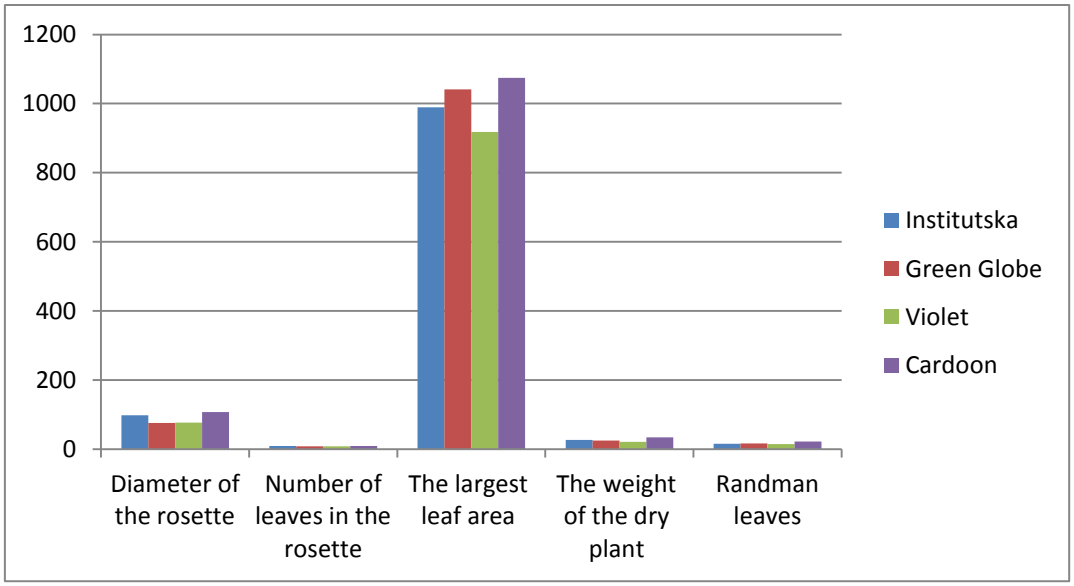

Graph 3. Graphical presentation of the results of the tested parameters at different genotypes of artichoke

Conclusion

The results of the first experimental year showed that different locations did not significantly affect the parameters tested. Sowing sites showed statistically significant differences. The thicker sowing proved to be worse for all the tested parameters. The variety Cardoon proved to be the best, then the variety of the Institutska, while the worst results were shown by Violet.The density of crops proved to be more cost-effective in the reed assembly. The variety Cardoon had on average the most extensive rosette, the largest surface of the largest leaf in rosette, the largest mass of dry plants and the best randman leaves. Variety Violet was the worst for all parameters except for the diameter of the rosette where the worst results were given by the Green Globe variety. Varieties of the Institutska and Green Globe are approximately uniform in terms of the mass of the dry plant and the randman of the leaves. Preliminary results indicate that the genotype shows the most significant differences in leaf yield. Spacing of sowing shows that a weaker yield in a denser structure could be assumed, since artichoke is a robust plant that requires a large living space. Locations did not show statistically significant differences, which supports the claim that genotype differences are key to yield. So far, it has been established that the most promising variety is Cardoon, which can be successfully cultivated in our agroecological conditions. The largest leaf yield is achieved by sowing at a distance of 70 cm x 30 cm.

Abstract

The aim of the study was to analyze the most important yield components and seed yield of selected red clover (*Trifolium pratense* L.) genotypes from Serbia and Bulgaria. Positive traits of individual genotypes could be the use in hybridization and the creation of new varieties, which, in addition to high forage yield potential would have a higher seed yield. The experiment was established in 2012 in Čačak on leached vertisol soil type with acid reaction (pH_{H2O} 4.8). Three genotypes isolated from the local populations and variety of K-39 were planted using a randomized block design with five repetitions, at a distance of 70x40 cm. Weed control was done mechanically. For the analysis of the yield and yield components was used the second cut in the second year of cultivation when usually done the production of seeds. The genotypes differed among themselves in each other's properties, except in a thousand seeds weight. The highest seed yield was achieved variety K-39 (19.8 g plant^{-1}), while the yield of other genotypes varied from 4.4 to 8.6 g plant^{-1}. Also, this variety had the highest values for most yield components. However, the genotype 3, which was isolated from the populations of Rozova dolina, had a significantly higher number of flowers per inflorescence (124.1), compared to the K-39 variety (89.4). The results suggest that certain genotypes could be used in further selection work in order to increase seed yield at already existing culivars.

Key words: *genotypes, red clover, seed yield, seed yield components*

Introduction

Red clover (*Trifolium pretense* L.) is one of the most important legumes for the production of quality forage. It grows in wild forms in meadows throughout Europe and Asia. Red clover seeds yield is mainly determined by the genetic basis of the variety, the ecological conditions of the area, the time of mowing, the presence of pollinator insects, as well as the interaction of the genotype and environment (Steiner et al., 1995). The high variability and genetic plasticity of the species are the result of the extremely xenogamous character of fertilisation and entomophilous pollination (Taylor and Smith, 1979). Due to the high variability and adaptability to the various environmental conditions, natural selection has produced a large number of local ecotypes, superior to the given growing conditions (Helgadottir, 1996).

Numerous studies confirm the advantage of local red clover's ecotypes in relation to materials from other regions, because acclimatized ecotypes achieve higher yields of forage and seeds than weaker acclimatized populations and varieties. Therefore, the choice of domestic varieties of perennial legumes, which are selected in the existing conditions, provides higher and more stable yields during their period of exploitation (Radović et al., 2004). Otherwise, a careful selection of red clover varieties can be one of the most important factors affecting yield, regeneration and potential profit (Drobna, 2009).

The aim of the study was to analyze seed yield and seed yield components of selected red clover genotypes in the area of Serbia and Bulgaria, as well as to select genotypes with higher

values for individual yield components. Such genotypes would represent a good basis for further work on hybridization and the creation of varieties that, in addition to the high potential for forage yield, would also have a higher seed yield.

Materials and methods

A field trial was conducted at the Veterinary Extension Service in Čačak (43°54'39.06" N, 20°19'10.21" E, 243 m a.s.l.) in 2012. The experiment was established on a leached vertisol (pH 4.8), which contained 3.18% organic matter, 0% $CaCO_3$, 22.08 mg extractable P 100 g^{-1} soil and 30.0 mg K 100 g^{-1} soil. Prior to seeding and in autumn, 45 kg ha^{-1} N, 45 kg ha^{-1} P_2O_5, and 45 kg ha^{-1} K_2O were incorporated into the soil.

One factorial experiment was set up according to a completely randomised block design in five replications (with 20 plants per plot at a plant spacing of 70x40cm). A total of four red clover genotypes, including the cultivar K-39 was used. Beside the K-39 cultivar (G_1), two genotypes were extracted from local populations from Bulgaria, Petrič (G_2) and Rozova dolina (G_3), as well as one genotype (G_4) isolated from the local populations in Serbia, the Municipality of Aleksandrovac (Central Serbia). Weeds were controlled mechanically. No irrigation was employed.

The mean annual air temperature in 2012 and 2013 was 13.12°C and 12.99° respectively and amount of annual rainfall 463.5 mm and 582.7 mm respectively. The average annual air temperature for the multi-year period (1992-2002) is 11.97°C, and the average amount of annual rainfall 680.3 mm.

The second growth in the second year (2013) was evaluated under field conditions for the following: stem number per plant, inflorescence number per stem, and inflorescence number per plant, using a sample of five plants per plot. Laboratory evaluation included determination of: flower number per inflorescence and seed number per inflorescence (using ten randomly selected inflorescences). Fertility (ratio between seed number and total flower number per inflorescence) and thousand seed weight (based on the seeds extracted from the same sample) are calculated. Seed yield components (inflorescence number per plant, seed number per inflorescence, thousand seed weight) were used to determine seed yield per plant which was calculated as g $plant^{-1}$.

The obtained results were subjected to a one-factor analysis of variance using SPSS software (1995). The significance of differences between mean values was tested by LSD test.

Results and discussion

The average number of stems per plant in this experiment was 37.7. The G-3 had the highest number of stems per plant, significantly higher than G-2 and G-4, while in relation to the cultivar K-39 it did not differ significantly (Table 1).

The significantly higher number of inflorescences per stem after had the K-39 variety as compared to G-4. The average number of inflorescences per stem was 5.84, and ranged from 4.0 to 7.44. Vasiljević et al. (2010) state that the average number of inflorescences per stem at the cultivar Una was 6.7, in the conditions of rare sowing (60 cm), which is significantly higher in relation to the plantation at a smaller inter-row spacing. A lower number of inflorescences per stem in this experiment is due to poor conditions of growth, first of all in terms of soil.

Thanks to the higher number of stems per plant and the number of inflorescences per stem, cultivar K-39 and G-3 had significantly higher number of inflorescences per plant compared to G-4. The average number of inflorescences per plant was 216.5. According to Montardo et al. (2003), the number of inflorescences per plant is one of the main components of the yield that needs pay attention in selecting red clover for a higher yield of seeds. Herrmann et al.

(2006) point out that the number of inflorescences per plant is the primary component on which seed yield depends.

The largest number of flowers per inflorescence, significantly higher than all other genotypes, had G3. The average number of flowers per inflorescence was 93.9, and it ranged in the interval from 78-124.1. However, G-3, contrary to expectations, did not have the largest number of seeds per inflorescence. The number of seeds per inflorescence in this genotype was significantly lower in relation to the K-39. The reason for this is significantly lower fertility of flowers in G-3 compared to K-39. The cultivar K-39 had a significantly higher fertility of flower, also in relation to the G-2. Oliva et al. (1994) state that the average number of flowers per inflorescence in the Kenland cultivar ranged from 101 to 142. According to Julen (1956) and Miladinović (1978), between red clover genotypes, there are large differences in the terms of number of flowers per inflorescence.

The average number of seeds per inflorescence in this experiment was 30.3. The average number of seeds per inflorescence at the variety Una at the inter-row spacing of 60 cm, according to Đukić et al. (2010) was 105.9. Wilczek and Cwintal (2008) state that the number of seeds per inflorescence at the variety Parada ranged from 61 to 74. The same authors claim that the number of seeds per inflorescence and the fertility of flowers are the most important seed yield components of red clover. Jevtic et al. (2007) and Wilczek and Ćwintal (2008) also show that the presence of insect pollinators has a major impact on the number of seeds per inflorescence. A smaller number of seeds per inflorescence in this experiment is also the result of poorer conditions for growing both in terms of soil and in terms of the lack of precipitation during the vegetation period. This is confirmed by Wilczek and Ćwintal (2008), according to which the fertility of red clover flowers varied from 51.2 to 69.8% in different years, and large amounts of rainfall during flowering can significantly reduce fertility and harvest yield in relation to the potential seed yield.

ANOVA 0,05	*	*	**	*	*	ns	**	*

SP – stems per plant, IS – inflorescences per stem, IP – inflorescences per plant , FI – flowers per inflorescence, SI – seeds per inflorescence, TSW – thousand seed weight (g), F - fertility (%), SP – seed yield per plant (g); Values followed by different small letters within columns are significantly different ($P<0.05$) according to the LSD test; **F test significant at $P\leq0.01$; *F test significant at $P\leq0.05$; ns – non-significant

In terms of the thousand seed weight, genotypes did not differ significantly among themselves. The average thousand seed weight was 1.48g.

The largest seed yield per plant as compared to the all other genotypes had K-39 (19.8 g plant^{-1}), while other genotypes did not differ significantly among themselves (their average yield was 6.5 g plant^{-1}). Herrmann et al. (2006) state that the average seed yield per plant in two genotypes of red clover was 5.72 g, with the variation interval of 0.71-11.31g. According to Vasiljević et al. (2000), the coefficients of genetic correlation show that seed yield per plant mostly depended on the number of seeds per inflorescence, the number of flowers per inflorescence and the number of productive stems per plant. The authors also claim that there are significant positive genetic correlations between the number of inflorescence and the

number of internodes per stem and yield of green matter, as confirmed by Steiner and Alderman (2003). Iannucci and Martinello (1998) came to the same conclusion, tracking three populations of the Mediterranean clover. The obtained results suggest that the simultaneous selection to the green forage yield and the seed yield is justified.

The obtained results indicate that the variety K-39 still had the highest seed yield in relation to the genotypes collected from natural populations. However, some genotypes had higher values for individual yield components than the K-39. In particular, the G-3 was highlighted here for the number of flowers per inflorescence. This indicates that in the existing cultivars, it is possible to continue to work on increasing the values for individual yield components in order to increase seed yield.

Conclusion

The red clover genotypes differed significantly among themselves in terms of all seed yield components except for the thousand seed weight. The largest seed yield had K-39 variety (19.8 g per plant). However, some genotypes had higher values for individual components of yield in relation to the cultivar K-39. G-3 here can be mentioned for the number of flowers per inflorescence. The obtained results indicate that with using red clover genotypes from natural populations, it is possible to work further on the increase of values for individual yield components, and thus the total seed yield per plant and per unit area.

Abstract

One of the most effective method in maize (*Zea mays* L) selection of adapted material is to create synthetic populations from inbred lines of known origin and superior properties. The methods used for inter- and intra-population synthetic improvement are some of the recurrent selection techniques. Success of recurrent selection depends on the choice of parent components and the method that will be used to obtain new inbred lines. The aim of this paper was to apply molecular markers for estimation of genetic variability of inbred lines, as potential parent components of synthetic populations. Molecular characterization of 26 inbred lines was done with 18 polymorphic SSR (*Simple Sequence Repeat*) markers. The total number of obtained alleles was 54, and ranged from two alleles for primers: phi033, phi036, phi087 and umc1013 to five alleles for primer umc1040. Genetic similarity values were calculated using Dice coefficient in the NTSYSpc2 program package. The highest similarity value (0.96) was calculated between inbred lines L22 and L24, while the lowest value (0.26) was between inbred lines L7 and L21. Cluster analysis divided the inbred lines into three groups mostly in accordance with their origin. The variability detected using SSR markers could be useful in selecting best parental combinations in creating synthetic populations.

Keywords: *inbred lines, synthetic population, SSR markers.*

Introduction

Maize is open-pollinated crop species with huge genetic diversity, containing wide variation in morphological traits and large-scale polymorphism on DNA level (Matsuoka *et al*., 2002). Long-term selection as well as development of modern maize hybrids have led to narrowing of the genetic variability of maize populations, i.e. to reducing the pre-conditions for the expression of heterosis. On the other hand, practical application of heterosis has been eliminated significance of the variety production and led to the genetic uniformity of the commercial material. Maize breeders are under constant pressure to create new commercial inbred lines, so they increasingly use F2 populations, reverse crossings and synthetic populations of narrow genetic bases in their programs, which has led to a reduction in the use of local populations as a carrier of high genetic variability (Ho *et al.*, 2005). Maize breeders recognized the importance of the genetic variability of the starting material for the expression of heterosis in the F1 generation. Molecular studies have confirmed that genetic divergence is positively correlated with heterosis (Ajmoone Marsan *et al*., 1998). For the successful program of creating synthetic populations as the source of new inbred lines besides choosing the selection method, the choice of parental components is very important. In order to study the genetic variability of the breeding material, divergence and belonging to heterotic groups, breeders can use data on the origin of the lines, test methods or genetic markers. Recently, in short-term selection programs, F2 generations and narrow base synthetic populations of narrow genetic bases are mainly used as a source of new lines. In contrast, long-term programs use synthetic populations and composites. It is very important to choose the right selection method of working with synthetic populations and parental components for their formation.

The use of molecular markers in diversity estimation and genetic structure is of great help when starting a selection program, creating synthetic populations as a working material and choosing the parents for that purpose. Due to the rapid developments in the field of molecular genetics, various types of techniques are used to estimate genetic diversity (Spooner *et al*., 2005, Semagn *et al.*, 2012, Dao *et al.*, 2014). *Simple sequence repeats* (SSRs) markers provides many advantages that make it especially applicable in studies of diversity and relationships, such as independence from environmental and pleiotropic effects, co-dominant inheritance, high reproducibility, locus specificity and their random distribution across the genome (Morgante *et al*., 2002; Barcaccia *et al*., 2006). The advantages of DNA markers in diversity estimation do not diminish the significance of phenotypic traits, on the contrary, morphological data provide practical information in characterisation of breeding material. In the past decade due to their high informativeness and reproducibility SSR markers become quite useful and frequently used PCR based markers in maize diversity studies (Dubreuil *et al*., 2006; Sharma *et al*., 2010). The objectives of this study were assessment of genetic diversity and relationships of inbred lines, as potential parent components of synthetic populations.

Materials and Methods

A set of 26 maize inbred lines from Maize Research Institute "Zemun Polje", which belongs to diferent heterotic groups and with different genetic background, was analyzed using molecular markers. Genomic DNA for each sample was isolated from seed bulk using the CTAB (cetyl trimethylammonium bromide) procedure according to Doyle and Doyle (1987). Molecular characterization was done with 18 polymorphic SSR markers (Table 1) from the maize germplasm bank (www.maizegdb.org). Polymerase chain reaction (PCR) was carried out in 25μL reaction volume containing: 50 ng of DNA sample, 1xBuffer, 0.8 mM dNTP, 0.5 μM of each primer pair and 1U *Taq* polymerase. The PCRs were performed in Thermocycler Biometra TProfessional Standard 96 using the following touch-down program: an initial denaturation at 95ºC/5min. by 15 cycles each of denaturation at 95ºC/30 s, annealing at 63.5/1min (-0.5ºC/cycle) and extension at 72 ºC /1min; and another 22 cycles of 95ºC/30 s, 56ºC/1min and 72ºC/1min. Final elongation was at 72°C for 4 min. The amplified fragments were separated by vertical electrophoresis (Mini Protean Tetra-Cell BioRad) on 8% polyacrylamide gel, with 100bp ladder as a marker. After staining with 0.5 μg/μL ethidium bromide gels were photographed under UV light on BioDocAnalyse Biometra. SSR profiles were scored as presence/absence of fragments in each sample and the data were assembled into a binary matrix. Genetic similarities between inbred lines were calculated by Dice (1945) and Unweighted Pair Group Method with Arithmetic mean (UPGMA) method was applied for cluster analysis. Statistical NTSYSpc2 program package (Rohlf FJ, 2000) was applied for marker data analyses.

Results and Discussion

Variability of initial genetic material is an important precondition for breeding. One way to increase the genetic variability of the breeding material is to create synthetic populations with a broad genetic base and to further apply the appropriate selection method. To determine the genetic similarity between 26 inbred lines, 18 SSR markers were used. Out of the 22 SSRs, four were not included in data analyses due to absence of amplification product (two primers) and poor amplification (two primers). Total of 54 alleles among the analysed 26 lines were identified. The number of alleles richness varied from two (phi033, phi036, phi087 and umc1013) to five (umc1040) with the average value of 3.15 per locus (Table 1). That is similar to previous study where Bantte and Prasanna (2003) reported 3.25 alleles using 36 SSR loci. Some other investigations have shown considerably higher number of alleles. Lu

and Bernardo (2001) obtained 4.9 alleles with 83 SSR loci, same as Warburton *et al*. (2002) with 85 SSR loci.

Table 1. List of 18 informative primers, with their chromosome position, repeat motif, number of alleles and allele range within analyzed inbred lines

	Probe	Bin	Repeat motif	Number of alleles	Allele range (bp)
1.	umc1013	1.08	(GA)9	2	120-160
2.	umc2047	1.09	(GACT)4	4	120-300
3.	umc1265	2.02	(TCAC)4	3	100-120
4.	umc2129	2.07	(CGC)5	3	90-110
5.	phi036	3.04	AG	2	60-80
6.	umc1350	3.08	(AG)13	3	140-160
7.	umc1418	4.08	(GGAAG)4	3	145-280
8.	umc1109	4.10	(ACG)4	4	100-120
9.	bnlg557	5.03	-	3	100-120
10.	phi087	5.06	(ACC)	2	150-180
11.	phi075	6.00	CT	3	200-220
12.	umc1006	6.02	(GA)19	3	100-120
13.	umc1015	7.03	(GA)45	3	90-110
14.	umc1782	7.04	(GAC)4	3	120-140
15.	bnlg2235	8.02	AG(23)	3	160-200
16.	phi033	9.01	AAG	2	220-240
17.	umc1040	9.01	CT11	5	80-200
18.	umc1492	9.04	(GCT)4	3	130-160

Genetic similarity (GS) values calculated by Dice (1945) between the pairs of all 26 inbred lines ranged from 0.26 (L7 and L21) to 0.96 (L22 and L24), with an average 0.55. The high value of genetic similarity between L22 and L24 can be explained by the same base population derivation. The largest part (53.5%) of obtained GS values was between 0.41 and 0.6 (Figure 1). The estimated average genetic similarity shows relatively high level of diversity among the analysed genotypes.

This study showed 9.8% of pairwise comparisions with GS values of GS greater than 0.7, making them a valuable source in creating synthetic populations. Beside genetic similarity of potential perental lines, their affiliation to heterotic groups should be considered.

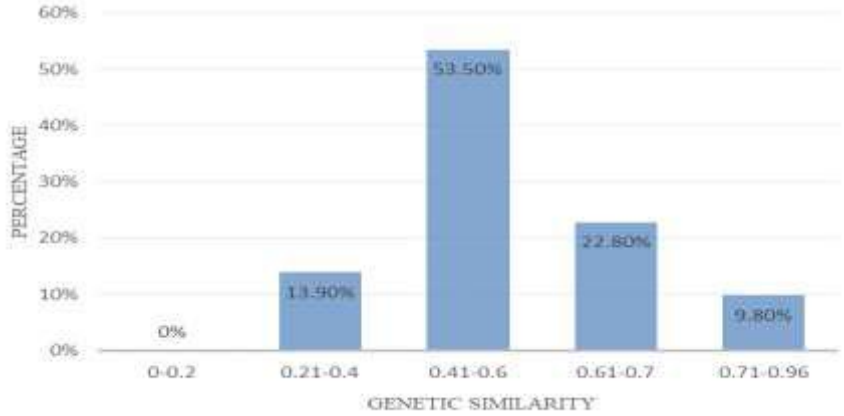

Figure 1. Dispersion og pairwise Dice's genetic similarity values of 26 maize inbred lines obtained from SSR data

The cluster analysis based on Dice′s genetic similarities distributed 26 inbred lines into three clusters (Figure 2) mostly in accordance with their origin. Cluster „A" was consisted of only two inbred lines (L1 and L19) with diferent background, quality protein maize (QPM) line with unknown genetic origin and Lancaster Sure Crop (LSC). QPM lines had unknown genetic orgin, so another goal was to classified them into appropriate heterotic group.
Out of the 26 inbred lines in total, twelve lines were grouped in cluster „B". The related lines belong to QPM lines (L2, L3, L4, L5 and L6), BSSS background mixed with other germplasm (L7, L9, L10, L11 and L25) and mixed local genetic basis and BSSS background (L13 and L18).

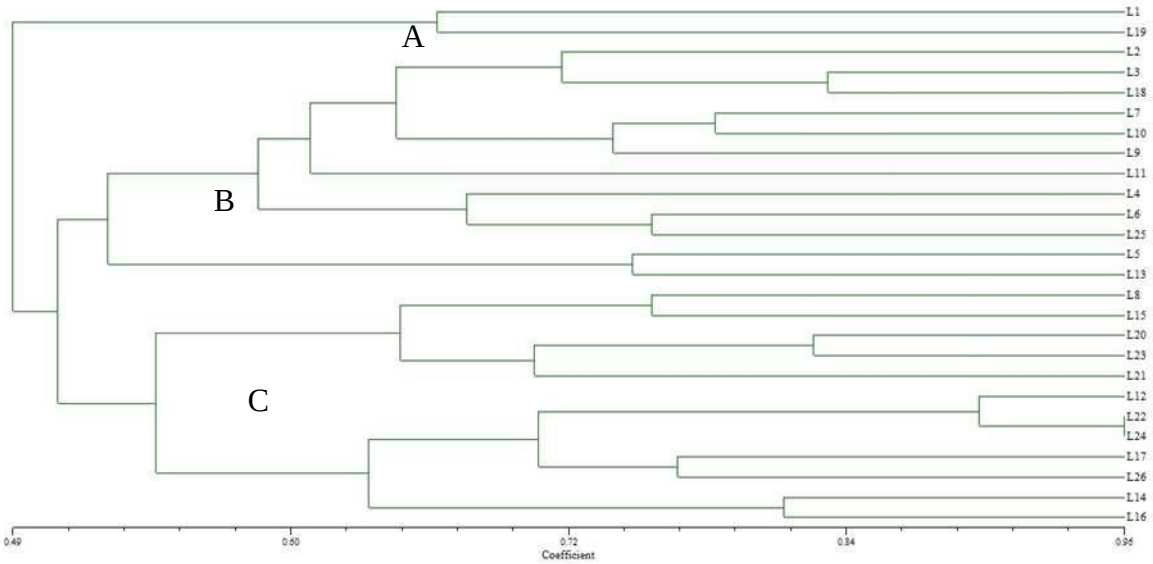

Figure 2. Dendrogram of 26 maize inbred lines constructed using UPGMA cluster analysis of genetic similarity values (Dice, 1945) obtained from SSR data
Remaining 12 genotypes formed cluster „C", which includes eight lines that belong to LSC germplasm (L12, L17, L20, L21, L22, L23, L24 and L26), three lines to BSSS (L8, L14 and L15) and one to local genetic basis (L16).
Using a small number of markers, it may be difficult to clearly evaluate the heterotic grouping due to the absence of some key loci for the differentiation of heterotic groups, indicating the use of larger number of markers.

Conclusions

Molecular marker analysis assigned the most of the inbred lines to their genetic background, substantiate them significant in evaluation of maize diversity. The variability detected using SSR markers could be useful in selecting best parental combinations in creating synthetic populations and new elite lines through breeding programs.

Abstract

Thanks to the high genetic potential for yield and favorable nutritional values, triticale is ranked among the perspective plant species.High and stable yields can be achieved under favorable weather conditions and with adequate agro-technology and variety selection.The paper presents the results of examining some morphological and productive traits of winter varieties of triticale cultivated in the north of Montenegro during the two vegetation season (2009/11). The experiment placed on a random block system in three repetitions, included five varieties of winter triticale(Odisey, Kg-20, Triumph, Rtanj and Tango). The applied agro-technology in the production of triticale was standard, with the application of NPK fertilizer combination 120:80:80. The following parameters were observed: height of plants, spike length, number of grains per spike, 1000 grain mass and grain yield of triticale. The results of the study showed significant differences in terms of the morphological and productive traits of winter triticale depending on the variety and weather conditions in the years of research. Variety Tango in both years achieved the highest yield (6841.6 kg ha^{-1}), while the lowest yield was recorded in Kg-20 variety (5216.6 kg ha^{-1}).Also, the variety Tango stood out significantly higher values for most other monitored parameters in both study years. The obtained results indicated that differences in the yields of the cultivars included in the research were the result of varietal specificity, which was mostly genetically conditioned.

Key words: *triticale, variety, morphological traits, productive traits*

Introduction

Triticale (Triticosecale Wittmack), a hybrid created by crossing wheat and rye, was designed with the idea to obtain a cereal, which combines good quality grain yield from wheat parents with tolerance to abiotic and biotic sress (Villegas et al., 2010). Ugarte et al, 2007; Estrada-Campuzano et al., 2008. reported that triticale is an interesting crop for unfavourable conditions where productivity of common crops is more or less limited. Modern triticale cultivars show higher yields and superior adaptation to soil quality and environments than wheat (Erekul and Köhn, 2006; Ugarte et al, 2007; Estrada-Campuzano et al., 2012). Varieties that are able to give high and stable yields in certain conditions have the highest value for production. Therefore, one of the most important tasks of selection and seed production consists of the fact that the proper sortsvarieties by natural ecological regions, taking into account the best adaptation to local conditions of each variety. The basic principle for determining the adaptation of varieties given conditions can be normal growth and development that ensures obtaining high and stable yields per year (Đurić N. et al., 2010).

The quality of triticale depends on the genotype and environmental conditions of their interaction and can be improved by applying nitrogen fertilizers. Biberdžić et al., 2013, point out that the yield was conditioned by the effect of a large number of factors which are most affected by cultivar, cultural practices and weather conditions during the experiment. Also, the same authors state that variety and agroecological conditions have a significant influence as well on the morphological characteristics of triticale.

The goal of our researh was to determine some morphological and productive characteristics of triticale in agroclimatic conditions of north Montenegro, depending on the tested variety.

Material and methods

In the experiment which was carried out in the period 2009-2011, in the north of Montenegro (vicinity of Bijelo Polje ,43º 01' 45" north latitude and 19º 44' 44" east longitude) on the alluvial type of soil, five cultivars of winter triticale were tested (Odysseus, Kg-20, Triumph, Rtanj and Tango).

The experiment was set out in randomized block system with three replications and experimental plot size of 6 m^2. Common technology for the production of triticale was used in the experiment. Sowing was carried out by manual method in optimal term (October). The other technology of production which was applied in the experiment was standard, with using of NPK fertilizer, combination 120:80:80. Phosphorus and potassium were used in equal amounts (80 kg ha^{-1}) before the sowing period, while the ½ of nitrogen was used before the sowing period and the rest of the planned amount was used as a fertilization at the end of March. Triticale harvest was performed in the stage of full maturity. At the same time plant height, spike's lenght, number of grains per spike, 1000 grain mass, hectoliter weight and grain yield were determined. The yield was adjusted to 14% moisture. The obtained results were statistically processed using method of variance analysis, whereby the significance of the average treatments were tested with LSD test, with significance threshold of 1 and 5%.

Soil and climatic conditions

The soil on which experiment was performed belongs to the alluvial type of soil. This soil is weakly calcareous, with the content of carbonate (2,4-2,44%) Based on pH value in saline extract the tested soil is of acid-based reaction (pH KCl 5,01-4,94). The soil is quite humic: 3,35-3,96 % with low phosphorus (5,12 – 4,24 mg/100g soil) and potassium content (7,5-3,8 mg/100 soil).

Table 1. Average monthly air temperature and precipitation amount (Podgorica Weather Bureau)

Year	Months										Sum
	X	XI	XII	I	II	III	IV	V	VI	VII	
Monthly rainfall (mm)											
2009-10	135	94	94	101	80	70	78	80	63	86	**881**
2010-11	65	131	147	36	76	31	46	121	33	79	**765**
1961-90	80	115	91	87	68	60	70	76	72	64	**783**
Average monthly temperatures (°C)									**Average**		
2009-10	9.77	5.95	4.06	1.31	2.4	6.39	10.93	15	18.11	20.95	**9.5**
2010-11	10.12	8.54	2.05	-0.65	0.94	6.03	10.54	14.5	18.9	21.23	**9.2**
1961-90	9.4	4.7	0.2	-1.3	0.7	4.9	9.0	13.3	16.3	17.9	**7.5**

Meteorological conditions, especially temperature and precipitation, are the main non-genetic factors that determine the success of cultivation of winter triticale and other small grains. In the growing season 2009/10 there was 881 mm of rainfall which is 116 mm more than in the second year of the research. Also, in October and November 2009/10 there was 229 mm of rainfall, which is 33 mm more than in the same period of 2010/11. From the data in the table it can be noted that the amount of rainfall in the period from April to June in the first year of research was higher compared to the second year of research. Considering that the amount of rainfall and temperature in these months are extremely important for development of small grains, the first year of research can be characterized as better in terms of weather conditions for growing triticale in this area.

Results and discussions

Morphological characteristics are mostly sort characteristics, although those are highly dependable of production conditions and practices applied (Biberdžić et al., 2013). The

following table shows some morphological and productive traits of winter triticale in regard to variety and climatic conditions in tested years.

Table 2. Some morphological and productive traits of winter triticale varieties

Cultivar (A)	**Winter triticale properties (2009/10)**				
	Plant height (cm)	Spike length (cm)	Number of grains per spike	1000 grain mass (g)	Grain yield kg ha^{-1}

The plant height of the triticale in our study was influenced by genotype and weather conditions during the growing period through the years of research.

An average plant´s height in the first year of investigation was 122.6 cm, in the second year was 120.4 cm. The average two-year values show that the Tango variety had a significantly higher stem height compared to other varieties included in the research.

Variation of plant height by varieties and years is partly the result of varietal specificities, i.e. genetic differences and part of the agroecological conditions of production. Favorable weather conditions during the winter months and spring part of the vegetation in the first year of the study caused a more intensive increase and a higher height of the stem compared with the height of the stem in the second year of the study. These results are in agreement with the results of Stošović (2009) and Ugrenović (2013) who emphasize that the weather conditions during the vegetation of the grain crops and therefore, the triticale, significantly influence the height of the plants, as well as the overall dynamics of growth and development.

In addition to the important role of the spike as a direct holder of the yield and its participation in the process of photosynthesis is also significant that in his position it least contributes to the shading of the lower parts of the plant. Spike′s length was determined by genotype in both years of research. The data in Tab.2 show that the greatest spike length, in both years of research, was in Tango variety. The Kg-20 and Triumph varieties had significantly shorter spike length than other tested varieties. Starting from the fact that the spike length is considered as an important factor of the fertility, the Tango variety proved to be the best from the aspect of achieving the highest yield in these agroecological conditions. Number of grains per spike represents quite a trait that is largely dependent on agro-ecological conditions, and cultural practices. The results show the existence of highly significant differences in the number of grains per spike among the tested varieties. The largest number of grains per spike was found in the Tango variety (41.6) in the first year of the study, and the smallest in the Triumph variety (26.9) in the second year of the study.

According to the Wiegand and Cuellar (1981) number of spikes and number of grains per spike are very important for yield which needs good weather conditions in different growth stages. 1000 grain mass is an important indicator of physical quality of grains. This is one of the properties that directly affect the grain yield. In average, the first year of investigation achieved higher value of 1000 grain mass than the second year, but there were no statistically significant differences. Also, the results of our research showed that there are significant differences in the values of 1000 grain mass among the investigated genotypes, which is in accordance with Jelic et al. (2002) who pointed out that the mass of 1000 grains is a varietal trait.

Grain yield is a complex feature of polygenic mode of inheritance. It is the resultant of the interaction of the variety, the applied agro-techniques and growing conditions throughout the entire life cycle. An average yield for all of five investigated varieties in the first year was 6334.0 kg ha^{-1}, which represents the difference of 616.7 kg ha^{-1} compared to the second year of studies. The differences in triticale grain yield between the experimental years resulted from the weather conditions. This finding was confirmed by the studies from other researches (Janušauskaitė, 2009, 2013). In our study, we also found significant influence of year on grain yield. Pecio (2010) reported that the highest grain yield was possible due to favorable moisture conditions during the whole growing period and smaller productivity of triticale resulted from worse moisture conditions. In both years of investigation variety Tango had significantly higher grain yield than on other varieties, while the lowest grain yield was found in variety Kg-20.

Conclusions

According to the results of the study the influence of the variety and climatic conditions on the morphological and productive traits of winter triticale, the following can be concluded:

- The plant height was conditioned by the variety, but also by the weather conditions during the vegetation period. The average values show that the Tango variety has achieved a significantly higher stem height in the two-year testing period.
- Favorable weather conditions in the first year of the study caused a significantly large difference in the average value of the spike length compared to the second year. The variety Tango had the highest spike length in both years of the investigation;
- The highest average number of grains per spike (36.3) was in the Tango variety, while on average the least number of grains per spike had the Triumph variety (27.5);
- The average weight of 1000 grains was higher in the first compared to the second year of testing;
- In the two years of the research, the Tango variety had a significantly higher value of the 1000 grain mass in comparison with other tested varieties;
- The average grain yield in the two-year trial was the highest in the Tango variety (6841.6 kg ha^{-1}), while the lowest average grain yield was recorded in the Kg-20 variety (5216.6 kg ha^{-1});
- The Average grain yield was higher in 2009 / 10th year compared to experimental 2010 / 11th year.
- According to all parameters, Tango variety was better than other varieties which were included in the testing. Tango variety is recommended for growing in this area.

Abstract

A complex and strategically structured research on oil-rich grain, vegetable and forage crucifers at the Institute of Field and Vegetable Crops in Novi Sad (IFVCNS) is based upon maintaining and sustainably utilising the germplasm collections of each crop. It comprises conventional and molecular breeding, biotechnology, agroecology, physiology, biochemistry, agronomy and seed science as well as commercial production for local and international markets. Here, we shall focus on oil-rich grain and forage crops, namely rapeseed, black and white mustards, forage kale and false flax. All collected accessions of our collection were phenotypically and cytogenetically characterized, including the monitoring and examining flower morphology, pollen features and number of chromosomes. The Mendel's rules are the basis of all the methods in breeding cultivars and hybrids of oil and forage crucifers. Constant and systematic use of these fundamental genetic postulates has led to the development and official registration of 13 autumn-sown rapeseed cultivars and two hybrids, two spring-sown rapeseed, one black mustard, one oil-rich grain white mustard, three autumn-sown forage kale and one spring-sown forage white mustard cultivar, as well as two false flax lines. Today, the conventional breeding methods are closely followed by various molecular genetic tools. So far, the most prominent role in assisting the selection of the genotypes with desirable traits has been played by RAPD and SSR molecular markers. A well-designed and feasibly organized integration of the Mendel's rules, conventional breeding methods and molecular breeding tools are anticipated as significantly improving the existing programmes. It ensures that the future efforts will yield further progress in oil and forage crucifers' research. This will benefit to various aspects of economy, especially the environment friendly production of quality oil for both human consumption and non-food industry and low-input and esteemed forage in ruminant feeding.

Mendelian rules in breeding of oilseed rape

Two years ago, 150th anniversary of Gregor Johann Mendel's paper "Experiments on Plant Hybridization" was celebrated. This famous scientist is recognized nowadays as father of genetics. He was studying inheritance of several traits (seed colour and shape, plant height, flower colour and position on plant, colour of unripe pod and pod shape) of pea (*Pisum sativum* L.). It took him eight years and only 2 hectares of monastery garden to plant around 28 000 of pea plants. Afterwards he deduced three Laws of inheritance (Law of dominance, Law of segregation and Law of independent assortment) that were not appreciated by scientific community at that time. It wasn't until 1990, that his work was rediscovered. His paper was considered premature, but became immortal work of the human spirit infiltrating into the mystery of life (Nemec, 1965).

Today, after century and a half, although a lot of new methods and techniques have developed, use of Mendelian rules is still actual and necessary for plant breeders. First

Mendelian Law of dominance is about trait dominance in offspring of parents that contained two opposite traits. One dominant allele for a trait masks phenotypic effect of recessive allele. This is exactly what happens in F_1 generation during hybrid development. Law of segregation tells about recombination in F_2 generation during meiosis which is of great importance for comprehension of the process of breeding lines. Finally, Law of independent assortment is a tool for combining different desirable properties by selection (Marjanović Jeromela *et al.*, 2016).

Mendel's rules enhance introduction of monogenic traits in rapeseed (*Brassica napus* L.). They are particularly useful in breeding for white flower trait (Huang *et al*., 2014), genic male sterility (Wang *et al*., 2007) or characters introduced by interspecific breeding e.g. resistance to clubroot (Diederichsen *et al*., 2009) and cabbage aphid (Quazi, 1988), pollen fertility gene (Yang *et al*., 1996), etc. In the last couple of decades, the regular use of Mendelian rules has contributed to the improvement of many rapeseed traits, including tolerance to biotic and abiotic stress, yield and seed quality (Ordon and Friedt, 1998).

Oilseed rape breeding in Serbia

At the beginning of 20th century, oilseed rape was main oil crop on Serbian fields. Later on, in the mid-1960s, it was observed that erucic acid can have toxic effect on humans when consumed in higher doses through vegetable oil in salads, cakes etc. Erucic acid is monounsaturated fatty acid that naturally occurs in oil-rich seeds of *Brassicaceae* family. After these findings, rapeseed production decreased significantly and sunflower got leading position as most planted oil crop in Serbia. Great efforts were made to lower erucic acid level from 50% to lower than 2% via selective breeding. Canadians were the first to achieve low content of erucic acid under 2% in spring rapeseed. They named this type of rapeseed Canola. Word canola is coined from "**Can**adian **o**il **l**ow **a**cid" and this oil had also low level of glucosinolates.

Glucosinolates are typically found in crucifers seed. They have high structural diversity due to modifications of side chain. Their taste is sharp bitter and when consumed by animals in higher amounts can be harmful for thyroid gland (Papas *et al*., 1979). Rapeseed with low erucic acid and low glucosinolates was marked in Europe as double zero canola (00). Breeding programme on oil-rich grain, vegetable and forage crucifers at the Institute of Field and Vegetable Crops in Novi Sad (IFVCNS) has begun in 1984 (Marinković and Marjanović Jeromela, 2006). In 1998, IFVCNS registered Banaćanka, first "00" rapeseed in Serbia (Marjanović Jeromela *et al*., 2007).

Two most important traits for crop breeding are yield and quality. Main goals of oilseed rape breeding include high oil yield in seed, optimal fatty acid composition, low erucic acid level, low glucosinolate content, optimal protein content, and better quality regarding amino acids (Friedt and Snowdon, 2009). When breeding oilseed rape for quality, development of high oleic acid (more than 75%) and low linolenic acid (less than 3%) (so-called HOLL) types is of high importance (Chungu *et al*., 2001). It was perceived that decreasing of linolenic acid and increasing of oleic acid in canola oil contribute to higher frying stability (Warner *et al*., 1997).

At the beginning of rapeseed breeding programme at the IFVCNS it was necessary to determine level of phenotypic and genetic diversity. Rapeseed has narrow genetic diversity because of intensive breeding for "00" types. Genetic diversity of our collection was assessed using RAPD (Random Amplified Polymorphic DNA) molecular markers. In this study, significant genetic variability between genotypes was recorded on morphological, biochemical and molecular levels, signifying their potential use in further breeding program of rapeseed (Marjanovic-Jeromela *et al*., 2009).

In order to avoid high temperatures and drought at the beginning of summer, which influence seed filling, rapeseed genotypes with early maturity are selected in breeding programmes.

Nevertheless, it is important to have genotypes resistant to major diseases (Delourme *et al*., 2012) and insects, to lodging and shattering. Due to adverse effects on bees, number of insecticides is restricted. Some insects have developed partial resistance to insecticides which will raise problems with increase of rapeseed production in Serbia.

In order to enable F_1 hybrid breeding there is need for efficient and trustworthy method for seed production (Yamagishi and Bhat, 2014). Cytoplasmic male sterility (CMS) is stable maternally inherited trait that is used for production of hybrid seed. Plants that have introduced CMS do not produce pollen, while the function of female organs remains unaffected. Ogura CMS and fertility restorer gene were introduced from radish into rapeseed via interspecific crossing (Bannerot *et al*., 1974) followed by protoplast fusion (Pelletier *et al*., 1983). Concerning that undesirable (fertile) plants need to be excluded on time, cytogenetical analysis of pollen presence and its viability (Atlagic *et al*., 2010) are viewed as methods of choice. Moreover, molecular markers are rutinely used for evaluation of presence and absence of cms gene in cms lines (Dimitrijević *et al*., 2015). Establishment of cms into breeding lines has led to first hybrid rapeseed at IFVCNS "NS Ras" that was registered in 2015.

So far, Institute of Field and Vegetable Crops has produced 11 varieties and 20 lines of spring type, and 56 varieties and 980 lines of winter type rapeseed. In Serbia and abroad 14 varieties of winter oilseed rape, two hybrids and two spring varieties have been registered so far.

False flax collection

Oil crops are cultivated world-wide and are important part of country economy. They are used for food production and non-food products. Oil of traditional crops and especially of alternative oil crops is very valuable and appreciated on market. False flax (*Camelina sativa* (L.) Crantz) is oil crop from *Brassicaceae* family used as food, feed and in industry. It is very adaptable species to different environmental terms and requires modest conditions for cultivation. Camelina is often planted on less productive and marginal fields. False flax is quite resistant to diseases, has low needs for inputs e.g. watering and nitrogen fertilizers. Joint false flax collection of IFVCNS and BOKU was phenotypically characterized to get better insight of false flax germplasm as potential source of desirable genes (Marjanović Jeromela *et al*., 2018b). Chemical analyses of oil and protein content as well as research of entomofauna of camelina were also carried out. Significant variability was found between tested genotypes regarding oil and protein content (Marjanović Jeromela *et al*., 2018a). Average oil content ranged from 30% to 50% (Marjanović *et al*., 2018b) which indicates possibility for further breeding on specific fatty acid and amino acid composition. This alternative oil crop has high value of meal with protein content that resembles soybean (Zubr and Matthäus, 2002). That is why it is considered as ideal meal for poultry and other livestock (Frame *et al*., 2007; Zubr and Matthäus, 2002). There is renewed interest in camelina because it has unique fatty acid profile with 30-40% of α-linolenic acid and around 15% of eicosanoic acid (Marjanović Jeromela *et al*., 2018b). Collected results confirmed that use of new methods and techniques for traits of interest and introducing new variability into collection are essential for effective breeding of this re-emerging crop.

Forage crucifers collection

Forage kale (*Brassica oleracea* L. var. *viridis* L.), turnip rape (*Brassica rapa* subsp. *oleifera* (DC.) Metzg.), brown (*Brassica juncea* (L.) Czern.), black (*Brassica nigra* L.) and white (*Sinapis alba* L.) mustards are crucifers mostly used as first fresh spring feed. Of all mentioned brassicas, forage kale is the most cultivated forage crucifer in Serbia. It is usually autumn-sown, with earliness and cold tolerance as the most important agronomic characteristics in breeding programmes (Mikić *et al*. 2014). Both black and white mustard seeds have lower level of oil content (28-42%) relating to other crucifer species. White

mustard has lower level of volatile oils and milder taste comparing to black mustard. It also has better tolerance to drought and heat in contrast to rapeseed which makes it better for cultivation on drylands (Slominski *et al*., 1999). White mustard has very shatter-resistant pods. Although black and white mustards have lower yield of fresh forage, their early maturity is what makes them advantageous for planting in early spring. Forage crucifers have lower dry matter content than forage legumes, ranging from 0.08% to 0.11% of forage dry matter (Mihailović *et al*. 2008), while, due to a high crude protein content in forage dry matter, they have moderately high crude protein yield (Ćupina *et al*. 2014) and thus may be successfully used not only in animal feeding, but also as green manure and other environment-friendly and ecological services (Antanasović *et al*. 2012). All forage crucifers are suitable for reliable forage production intercropped with legumes (Marjanović Jeromela 2017). The accessions of mustard germplasm collection at IFVCNS are being routinely examined for following traits: flower morphology, pollen viability and number of chromosomes. So far, IFVCNS has registered three autumn-sown forage kale varieties, namely NS-Bikovo, Perast and NS Rani, one spring variety of forage white mustard "NS Gorica", one spring variety of grain white mustard "Bela" and one spring variety of black mustard "Crna".

Conclusions

Complex and strategically structured research at the IFVCNS was based upon maintaining and sustainable use of germplasm collections of each crop. It comprised conventional and molecular breeding, biotechnology, agroecology, physiology, biochemistry, agronomy and seed science as well as commercial production for local and international markets. Nowadays, when genome of oilseed rape is sequenced it is expected that new findings on genome organization and structure will benefit to breeders and enhance genome assisted selection. Mendelian rules will continue to assist in development of new *Brassicaceae* cultivars.

Abstract

The effect of genotype and seeding rate on the yield and quality of sainfoin (*Onobrychis viciifolia* Scop.) forage was examined in agroecological conditions of South Serbia. The Makedonka cultivar of sainfoin, as well as the local population Sokobanja, were sown at different rates: 100, 120 and 140 kg/ha. The average forage yield of 47.7 t/ha^{-1} was measured over the course of three years. The sowing year yielded the least amount (30.2 t ha^{-1}), with the maximum amount being recorded in the second year (67.2 t ha^{-1}) of research. The Makedonka yielded a three-year long average of 49.1 t/ha^{-1}, while the Sokobanja yielded an average of 46.3 t ha^{-1} during the same period. The 120 kg ha^{-1} showed to be the most effective seeding rate, with the highest forage yields of 50.8 t ha^{-1} (Makedonka) and 47.4 t ha^{-1} (Sokobanja), while the highest seeding rate (140 kg/ha) showed to result in the least amount of forage yield: 4.,5 t ha^{-1} (Makedonka) and 44.8 t ha^{-1} (Sokobanja). In terms of the dry matter quality, the Sokobanja culture was distinguished by slightly higher contents of crude protein than those of Makedonka (19.3% vs 18.4%), as well as lower contents of crude cellulose (26.5% vs 27.3%).

Keywords*: Sainfoin, Forage yield, Dry matter quality*

Introduction

Sainfoin is a very old culture that was also considered to have medicinal properties in ancient times. It was first grown in Mediterranean, a few thousand years ago. According to Delgado (2008), it first began to serve as fodder in the Middle Ages, in France. It soon spread throughout the entire Europe, and later on the world, as well. Today, it is grown on larger areas in moderately warm parts of Europe, Mediterranean countries, Russia, Asia, and western parts of North America (Smoliak *et al.,* 1972). In Serbia, it is grown less, and mostly in southern and south-eastern regions of the country (Vučković, 1999).

In arid, as in semi-arid, regions, on shallow, rocky and poor lands, red clover and alfalfa cannot even compete with sainfoin. In conditions like these, sainfoin is almost the only culture that can be grown successfully. It features a strong root system, which it uses to permeate the soil, so it can successfully be used as a protector of erosion. Thanks to the symbiosis with nitrogen fixating bacteria, sainfoin takes in significant amounts of nitrogen and provides the soil with the feed for the next crop (Kral and Delaney, 1982). Compared to alfalfa and red clover, sainfoin suffers less damage from dodder. It is also more resistant to pests than alfalfa, especially to the alfalfa weevil (*Hypera postica*), which causes a decrease in production (Morill *et al*., 1998, Mohajer *et al*., 2011). Sainfoin does not cause bloating in cattle, so biomass can therefore be used completely safely (Howarth *et al*., 1978). It can be used for both grazing and mowing, and it is also resistant to trampling. It yields great results if sown with grasses as well as in pure sowing. It is's also significant as honey plants.

Despite all the mentioned positive characteristics and yields of dry matter of 12-14 t ha^{-1} in agroecological conditions of Serbia (Ćupina *et al*., 1999, 2010), sainfoin does not take on significant areas. The main reason for such state is the advantage that alfalfa has over sainfoin

(high yield, quality) when it comes to cultivating, but also the lack of profitable seed production, i.e. low seed yields (Stević *et al.*, 2012). Next to this, higher seed quantities are needed for a good crop establishment of sainfoin. According to numerous studies, next to the climate factors, the method and row spacing of sowing also have significant effects on the sainfoin biomass yield. The amount of seeds used for sowing is a very significant factor in the production of sainfoin, especially when keeping in mind that insufficient amounts are caused by low seed yields. The average amount of seeds needed for sowing of sainfoin ranges from 100 to 150 kg ha^{-1} (Vučković, 1997). Ćupina and Erić (1999) point out that the highest yields of the sainfoin forage are achieved by sowing at 140 kg ha^{-1}. Seed yields above 160 kg ha^{-1} are reflected negatively on the sainfoin crop as such sowing increases competition between the plants (Ćupina *et al.*, 2010).

The goal of this research was to examine the effects of genotype and amount of seeds on the yield and quality of sainfoin biomass in agroecological conditions of southern Serbia, which would represent a meaningful addition to the knowledge towards the advancement of cultivation, as well as an increase of the area covered with this significant plant species.

Material and Methods

In order to accomplish the goals set for the period ranging between 2011 and 2013, a three year-long experimental research has been conducted in Donje Medjurovo, close to Niš.

As material, the Makedonka cultivar as well as the local population Sokobanja. Seeds were sown by hand on April 22nd, 2011. Sowing was done at 100, 120 i 140 kg ha^{-1} of kernels with 20 cm - spacing. The base plot was 5 m^2 in area size (5x1). The experimental research was set using a random block system with 4 repetitions. In the sowing year, sainfoin was mowed two times, while it was mowed four times the following two years. Mowing was done at the stage of technological maturity for forage production, that is at the beginning of the flowering stage. For the dry matter quality analysis, samples from the first cut in 2012 were used. Dry matter was analysed for total nitrogen by the Kjeldahl method (InKjel 450M), crude protein (CP) using the formula N(%) × 6.25, crude fibre (CF) by the Scharner-Kurschner method, crude fats (CFs) by the Soxhlet method (KEX 100F Soxlet, Behr), and ash (A) by ignition at 550 °C to constant weight.

The measured green forage yields is analysed using the ANOVA variance analysis, while the significant difference between the resulting values are established using the LSD test. For dry matter quality properties the coefficient of variation (CV) is established.

The soil used in the study is that of the alluvial type. When it comes to pH values, they were reported as neutral, with moderate content of organic matter (2.83%). Nitrogen levels of the soil are moderately (0.14%), while the phosphorus (18,6 mg/100 gr P_2O_5) and potassium (21,5 mg/100 gr K_2O) levels are highly satisfactory. The preceding crop was winter wheat

Based on data collected over multiple years, the area surrounding Niš is characterized by a long dry summer period, spanning through all summer months. However, the 2011 (sowing year) is characterized by a very dry spring, pointed by the fact that April barely yielded 12.5 mm precipitation, which caused a late sowing and slowed down growth (Table 1). Still, thanks to the rainfall during the month of May, a satisfactory early plant growth was recorded. The year of 2012 is characterized by a rainy May (162 mm), dry June (5.9%) and August (10.6 mm, while during 2013, the rainfall was significantly more favorably spaced out during the vegetative period (Table 1).

Table 1. Mean monthly temperatures (^{o}C) and total precipitation (mm)- Niš 2011-2013

Year	I	II	III	IV	V	VI	VII	VIII	IX	X	XI	XII	I-XII Aver./ Amou-nt

Results and Discussion

During the three-years research done in agroecological conditions of southern Serbia, an average annual green forage yield of sainfoin of 47.7 t ha^{-1} was measured (Table 2). Per year, the highest yield was measured in 2012 (67.2 t ha^{-1}), followed by yields recorded in 2013 (45.6 t ha^{-1}), and finally, the lowest yield was measured in the sowing year (30,2 7 t ha^{-1}) of 2011, as expected. Looking at the effects of genotype on green forage yields of sainfoin, the Makedonka cultivar measured a higher yield (49.1 t ha^{-1}) than that of the local Sokobanja population (46.3 t ha^{-1}). In all three years of research the Makedonka sainfoin cultivar achieved higher yields, however the difference was not statistically significant, compared to the local population Sokobanja (Table 2). Significantly lower sainfoin yields in the hilly areas are reported by Mijatovic (1975), according to whom an average four-year-long green forage yield of sainfoin was recorded at 34.1 t ha^{-1}. Similar results (23.2 t ha^{-1}) in hilly-mountainous conditions are reported by Bekovic et al. (2015). In a three-year-long research conducted by Liu *et al.* (2008), depending on the time of sowing, a green forage sainfoin yield of 38,2 t ha^{-1} (sown in April) and 49,8 t ha^{-1} (sown in May) was reported, which is comparable to the present study's results. The same authors suggest that the effect of genotype is not crucial to the sainfoin forage yields.

A significantly higher effect on sainfoin forage yields had the amount of seed used for sowing, as well plant density. The highest three-year-average yields were recorded while sowing at 120 kg ha^{-1} (49.1 t ha^{-1}), somewhat lower at 100 kg ha^{-1} (48.3 t ha^{-1}) and lowest at 140 kg ha^{-1} (42.6 t ha^{-1}). Sowing at 120 and 100 kg ha^{-1} there were no statistically significant differences in forage yields, while both amounts of seeds resulted in statistically significantly higher yields, compared to the yields from sowing at 140 kg ha^{-1}. Going by the years, the sowing year did not show any statistically significant effect of the amount of seeds on the sainfoin forage yields, while the second (100 kg ha^{-1}) and third year (120 kg ha^{-1}) showed statistically significantly higher yields compared to sowing at 140 kg ha^{-1} (Table 2).

Table 2. The effect of genotype and seeding rate (kg ha^{-1}) on sainfoin forage yield (t ha^{-1})

Year	Genotype	Seeding rate			
		100	120	140	Average A

Examining the effect of the seed amount on sainfoin forage yields Ćupina *et al.* (2010) achieved the highest yields sowing at 120 kg ha^{-1}, compared to sowing at 80 and 140 kg ha^{-1}. However, the authors conclude that this sowing norm has not provided a statistically significant difference in green forage yields, compared to the norm of 80 kg ha^{-1}. Keeping in mind these conclusions, as well as the results achieved in the present study, lower norms of seeds are recommended for sowing sainfoin, which in turn proves favorable, considering the lack of sufficient seed amounts of this significant plant species.

Looking at dry matter quality of the examined genotypes of sainfoin, somewhat greater differences in crude protein and cellulose contents stands out, while other quality parameters showed little to no difference (Table 3). Local population Sokobanja had higher contents of crude protein (19.3%), and lower contents of crude cellulose (26.52%), as compared to the Makedonka cultivar (18.4% and 27.3%). Somewhat significant differences were reported for these properties as well (CV =2,68% for crude protein, and CV= 1,84 % for crude cellulose).

The average crude fats content in the Makedonka cultivar was measured at 4.06%, whereas that number was 4.18% in Sokobanja. The ashes content was 6.81% in Makedonka, and 7.65% in Sokobanja.

Table 3. The effect of genotype and seeding rate (kg ha^{-1}) on sainfoin forage quality

Genotype	Seeding Rate	Crude proteins (%)	Crude cellulose (%)	Crude fats (%)	Ash (%)
Makedonka	100	18.41	27.55	4.02	6.80
	120	18.22	27.50	4.10	6.85
	140	18.57	26.85	4,05	6.78
	Average	18.40	27.30	4.06	6.81
Sokobanja	100	19.25	26.61	4.20	7.65
	120	19.33	26.48	4.15	7.55
	140	19.32	26.47	4,18	7.59
	Average	19.30	26.52	4.18	7.60
CV		2,68	1,84	1,76	1.45

As expected, the plant density seed amount did not have a significant effect on the quality of dry matter in examined sainfoin genotypes. Similar results are reported by Stevovic *et al.* (2010), according to whom the crude protein contents ranged from 18.54 % (cultivar EG Norm), to 19.94 % (Sokobanja). The crude cellulose content ranged from 26,72 % (Sokobanja) to 28,30 % (EG Norm). The crude fats content ranged from od 4.10 % (EG Norm) to 4.24 % (Sokobanja), and ashes content ranged from 6.56 % (EG Norm) do 7.80 % (Sokobanja). Row spacing did not have any significant effect on the chemical composition of the sainfon dry matter.

Conclusions

Based on the results reported in the study, the following conclusions may be drawn:

In agroecological conditions of southern Serbia, a three-year-long average of green forage sainfoin yields was measured at 47.7 t ha^{-1}. The Makedonka cultivar had higher yields (49.1 t ha^{-1}) than the local cultivar Sokobanja (46.3 t ha^{-1}), with no statistically significant differences reported in the study. The highest three-year-long yields were achieved by sowing at 120 kg ha^{-1} (49.1 t ha^{-1}), somewhat lower at 100 kg ha^{-1} (48.3 t ha^{-1}), and lowest at 140 kg ha^{-1} (42.6 t ha^{-1}). The differences in yields achieved by sowing at 100 and 120 kg ha^{-1} were not statistically significant, hence lower seed amount can be recommended (100 kg ha^{-1}). When it comes to dry matter quality, the Sokobanja cultivar stands out with a higher content of crude proteins and lower content of crude cellulose (19.30 % and 26.52 %), compared to the Makedonka cultivar (18.40 % and 27.30 %).

Abstract

The Čačak region (central Serbia) is famous for apricot growing, accounting for about 10% of total apricot production in Serbia, with 3–4,000 t of fruit produced in high-yield years. Research was conducted from 2008 to 2012 to evaluate a large number of apricot genotypes in the region. Five genotypes exhibiting the best performance were singled out and marked with the letters GG and the numbers 1–5. This paper presents two-year results on the properties of these genotypes and their comparison with cv. 'Roxana' used as the control. Phenological characteristics (flowering and ripening), leaf traits and fruit attributes were assessed. The results showed that, compared to the control, all apricot genotypes began to flower 2 to 3 days earlier and were similar in both the progress and abundance of flowering. The onset and termination of ripening in all genotypes were 5 to 6 days earlier than in the control cultivar. As far as leaf properties are concerned, the genotypes GG_1 and GG_2 had larger leaf dimensions compared to the control. The petioles in all genotypes were shorter and had fewer glands than those of 'Roxana'. Regarding fruit dimensions and fruit weight, the fruit size of GG_5, followed by GG_4, was similar to that of 'Roxana', whereas the other genotypes had smaller fruit dimensions and lower weight. Soluble solids content was highest in GG_1. There was no significant difference in this trait between 'Roxana' and the tested genotypes. Overall, the largest number of positive properties was found in GG_5 and GG_4, which could be used as experimental material in further research, as well as for orchard establishment.

Keywords: *Apricot, genotype, phenological properties, fruit traits*

Introduction

Apricot (*Prunus armeniaca* L.) originates from western China, where apricot kernels have been found dating back to 5,000 or 6,000 B.C. The natural gene centres of origin of apricots are the Tian Shan mountains, the Sungari and Amur River valleys, parts of Manchuria and the region around Beijing (Milošević, 1997). Apricots are widely grown today in the Mediterranean countries, as well as in Iran, Pakistan and Uzbekistan. Turkey is the largest apricot producer, with the total annual production of 695,364 t (FAOSTAT, 2014). In terms of apricot acreage, Serbia ranks eighth in Europe. Central Serbia, particularly the Čačak region, is rich in biodiversity as a source of apricot germplasm; hence the abundance of different genotypes, varieties and forms. There is a large number of individual apricot trees, in gardens, fields or neglected areas of land, which are grafted using unknown material, mostly on myrobalan plum (*Prunus cerasifera* Ehrh) or 'Belošljiva' (*Prunus domestica* L.). Some of these trees have positive biological and pomological traits, and are gladly chosen for plantations around Čačak, where they are grown under different local names and equally distributed along with the most dominant cultivars, such as 'Hungarian Best', 'Roxana' and the Novi Sad cultivars 'NS 4' and 'NS Rodna' (Milošević *et al*., 2009, Milošević *et al*., 2011). The objective of this study was to assess the selected apricot genotypes in the Čačak region, focusing on their phenological and pomological traits. The selected genotypes can be used for

future breeding work, and can also be grown in new apricot orchards under similar environmental conditions.

Material and Methods

The research was conducted in an apricot orchard in the village of Gornja Gorevnica located 9 km northwest of Čačak (20°57'48" N; 20°19'31" E; 396 m a.s.l.). Apricot trees were grafted high above ground level (60-80 cm) on the 'Belošljiva' vegetative rootstock, and were planted at a spacing of 5 × 4 m (500 trees ha^{-1}). The vase training system with 3-4 scaffold branches was employed. The cultural operations common in intensive apricot orchards were used, without irrigation (due to lack of sufficient amounts of water and consequential irrigation irregularity).

The farm household where the research was conducted is traditionally engaged in apricot growing. In 2005, 2006 and 2007, scions were collected from the best oldest apricot trees from this and surrounding farms to perform grafting for orchard establishment. In autumn 2008, a new orchard was established for research purposes. During initial years after planting, trees were monitored for growth and development, coming into bearing, vitality and other properties. After 4 years (in 2012), 8 trees having positive traits and good initial cropping were singled out. In the following year (2013), 5 trees repeated their positive traits; therefore, these trees were marked as genotypes for future research and observation. The genotypes were marked with the numbers 1-5, preceded by the letters GG, abbreviated from Gornja Gorevnica, the village where they were singled out (GG 1, GG 2, GG 3, GG 4 and GG 5). The genotypes were singled out for their large fruit weight, great initial cropping and high vitality during initial years after planting. The trees were marked and analysed in the following year (2014), in the 6th growing season of the orchard. The genotypes were compared with cv. 'Roxana' (control).

The genotypes were characterised and evaluated in accordance with the Apricot Descriptor (Guerriero and Watkins, 1984).

The analysis focused on:

-Flowering (beginning, full, end and abundance);

-Fruit ripening (beginning, end);

-Leaf and petiole traits (length, width, number of glands on the petiole)

-Fruit traits (dimensions, weight, stone weight, soluble solids content (^{o}Brix).

Leaf and petiole lengths (mm) were measured by a ruler, and fruit dimensions were taken by an INOX 1/20mm calliper. Fruit and stone weights were measured using a KERN FCB precision balance (Kern & Sohn GmbH, Belingen, Germany) with a weighing range of 6,100 g and an accuracy of ±0.2 g. Soluble solids content (^{o}Brix) was assessed by a Milwaukee MR 200 hand refractometer (ATC, Rocky Mount, USA). The obtained data were subjected to statistical analysis by calculating the mean value, and its absolute variation was determined by the standard error of the mean (±SE). The statistical analysis and testing of the significance of differences were performed by the analysis of variance and LSD test at a significance level of $P \leq 0.05$ using the Statistica statistical software, Version 5.0 (SPSS for Windows, Chicago, Illinois,USA).

Results and Discussion

The results on the beginning of flowering, full flowering and end of flowering, as well as on the abundance of flowering, are presented in Tab. 1.

Tab. 1. Flowering of apricot trees

Genotype (cultivar)	Flowering			
	Beginning	Full	End	Abundance
GG 1	14 March	17 March	22 March	4
GG 2	15 March	18 March	22 March	4
GG 3	15 March	18 March	23 March	3
GG 4	14 March	17 March	22 March	4
GG 5	14 March	17 March	22 March	4
Roxana	17 March	20 March	27 March	4

The beginning of flowering in the studied genotypes ranged over a short period from 14 to 15 March, the earliest (on 14 March) in GG1, GG4 and GG5, a day later in GG2 and GG3, and the latest in the control cv. 'Roxana' (17 March). Full flowering was first reached in GG1, GG4 and GG5 on 17 March, followed by GG2 and GG3 on 18 March, whereas the latest full flowering date was observed in 'Roxana' on 27 March. The end of flowering date showed the same pattern: flowering ended first in GG1, GG2, GG4 and GG5 on 22 March, followed by GG3 on 23 March and 'Roxana' on 27 March. The analysis of the results revealed that the shortest flowering was in GG2 (7 days) and the longest in 'Roxana' (10 days). The abundance of flowering was lowest in GG3 (rating: 3), as opposed to the higher identical abundance of flowering in the other genotypes (rating: 4). As shown, differences in the beginning and end of flowering dates among genotypes were not significant, and were characteristic of 'Roxana' and the genotypes analysed (Milošević, 1997). This subject has also been dealt with by Milatović *et al*. (2015). In their research, the average flowering time was at the end of March and beginning of April. Flowering time differed across years, as also found by Vachun (2003). Mehlenbacher *et al.* (1991) observed that the beginning and course of growth stages are affected by a multitude of factors. Ripening time in the tested genotypes and the control cultivar is presented in Tab. 2.

Tab. 2. Fruit ripening of apricot trees

Genotype (cultivar)	Fruit ripening	
	Beginning	End
GG 1	9 July	18 July
GG 2	9 July	18 July
GG 3	10 July	20 July
GG 4	9 July	19 July
GG 5	9 July	19 July
Roxana	15 July	24 July

The beginning of ripening was earliest in GG1, GG2, GG4 and GG5 (on 9 July), followed by GG3 (10 July), and latest in 'Roxana' (15 July). End of ripening occurred first in GG1 and GG2, then in GG4 and GG5, followed by GG3 and 'Roxana', which ended its ripening on 24 July. The longest fruit ripening period was in GG3, GG4 and GG5, i.e. 10 days, and somewhat shorter (a day shorter) in 'Roxana' and GG1 and GG2. As shown by the results, there were no considerable differences in fruit ripening time between the genotypes and 'Roxana'. In apricot, more than in other fruit crops, the choice of rootstock has a decisive effect on cropping and fruit quality and ripening (Mišić, 1984). The beginning and course of fruit ripening are determined by genotype and growing conditions. Depending on cultivar, the fruit development and ripening period (from flowering to fruiting) lasts for 71–121 days (Pejkić and Ninkovski, 1986), as also confirmed by the present research. The fruits

of 'Hungarian Best', from which the genotypes tested in this study originate, ripen in the second ten-day period in July, and those of 'Roxana' about 7 days later (Milatović, 2013). These results are supported by the findings of the present study.
Leaf characteristics are given in Tab. 3.

Tab. 3. Leaf and petiole characteristics

	Leaf dimensions			Petiole	
	Length (mm)	Width (mm)	C[1] (mm)	Length (mm)	Glands
GG 1	89.65±5.40 a	71.76±6.04 a	35.18±1.90	49.68±3.12 cd	2.55±0.09 b
GG 2	91.18±6.20 a	73.16±5.02 a	35.83±2.11	52.76±2.70 b	2.26±0.11 c
GG 3	85.23±6.11 b	71.26±5.20 a	33.96±1.95	53.50±2.71 b	2.00±0.08 d
GG 4	79.30±5.11 c	67.36±3.80 ab	30.70±2.15	51.15±4.33 bc	1.55±0.10 e
GG 5	86.41±6.03 b	68.06±4.05 ab	33.83±1.75	54.73±2.70 ab	2.15±0.09 c
Roxana	86.93±4.11 b	64.77±2.23 b	36.35±3.09	58.83±3.90 a	4.25±0.17 a

The different lowercase letters in columns show significant differences between means at $P \leq 0.05$ according to LSD test
[1] distance of the widest part of the blade from the leaf blade base

Leaf length in the examined cultivars ranged from the smallest in GG4 (79.30±5.11 mm) to the greatest in GG2 (91.18±6.20 mm) and GG1 (89.65±5,40 mm). As compared with the control, leaf length was significantly greater in GG1 and GG2, and significantly smaller in GG4. The largest differences in leaf width were observed between 'Roxana' leaf as the narrowest (64.77±2.23 mm) and GG2 leaf as the widest (73.16±5.02 mm). In comparison to 'Roxana', GG4 and GG5 showed no significant difference in leaf width. As regards the distance of the widest part of the blade from the leaf blade base, there were no significant differences between the genotypes and cv. 'Roxana'. Petiole length varied from 49.68±3,12 mm (in GG1) to 58.83±3,90 mm (in 'Roxana'). A significant difference was also observed between the other genotypes and 'Roxana', which had the longest petiole, with the exception of GG5, which also had a long petiole. The number of glands was lowest in GG4 (1.55±0.10), and the highest in 'Roxana' (4.25±0.17). All tested genotypes had a significantly lower number of glands on the petiole in comparison to 'Roxana'. The morphological characteristics of the fruit of the studied genotypes (fruit height, thickness and width) are given in Tab. 4.

Tab. 4. Fruit dimensions

	Fruit dimensions		
	Height (mm)	Width (mm)	Thickness (mm)
GG 1	45.20±2.66 c	45.26±2.11	44.38±2.70 c
GG 2	47.93±3.71 bc	46.52±3.90	46.21±2.19 c
GG 3	48.59±4.02 b	47.39±3.80	45.10±2.60 c
GG 4	49.86±3.80 b	50.65±3.80	51.37±2.77 a
GG 5	53.52±2.55 a	51.80±2.66	49.51±3.90 b
Roxana	50.75±3.22 ab	48.22±3.23	47.14±3.90 bc

The different lowercase letters in columns show significant differences between means at $P \leq 0.05$ according to LSD test

Fruit height ranged from 45.20±2.66 mm in GG1 to 53.52±2.55 mm in GG5. In comparison to 'Roxana', significantly lower values were measured only in GG1. Variations were also observed in fruit width, i.e. between 45.26±2.11 mm in GG1 to 51.80±2.66 mm in GG5. In this case, when compared with 'Roxana', fruit was wider in two genotypes and narrower in three, with no significant differences. Fruit thickness values were lowest in GG1 – 44.38±2.70 mm, followed by GG3 – 45.10±2.60 mm and GG2 – 46.21±2.19 mm. 'Roxana' followed with

47.14±3.90 mm, and values greater than the control were measured in two genotypes - GG5 49.51±3.90 mm and GG4 51.37±2.77 mm. Similar results on fruit dimensions were reported in a study by Milatović *et al.* (2014): fruit height 42.5–50.5 mm, fruit width 41.1–50 mm and fruit thickness 37.3–46 mm. Results on fruit weight, stone weight and chemical characteristics of the fruit are presented in Tab. 5.

Tab. 5. Fruit and stone properties

Genotype (cultivar)	SSC (°Brix)	Fruit weight (g)	Stone weight (g)	Flesh/stone ratio (%)
GG 1	15.06±1.10 a	68.08±5.17 b	3.81±0.17 c	94.40
GG 2	11.18±0.89 c	66.35±4.90 b	4.37±0.22 a	93.41
GG 3	12.85±0.90 b	61.49±4.45 c	3.80±0.25 c	93.82
GG 4	13.13±0.59 b	75.12±6.15 a	4.22±0.35 a	94.38
GG 5	13.27±1.07 b	72.46±5.60 ab	4.00±0.31 b	94.47
Roxana	13.31±1.07 b	76.05±6.03 a	3.96±0.27 b	94.79

The different lowercase letters in columns show significant differences between means at $P \leq 0.05$ according to LSD test

Soluble solids content in this study was 11.18±0.89 °Brix in GG2 and 15.06±1.10 °Brix in GG1, whereas the other genotypes had values within this range and were not significantly different from 'Roxana', as opposed to GG1 and GG2. Soluble solids (mostly containing sugars) and acids indicate fruit sweetness (Milatović, 2013). These fruit attributes have been the subject matter of a number of studies (Ayanoglu and Kaska, 1995; Licznar-Małańczuk and Sosna, 2005). Milošević *et al*. (2009) reported the lowest soluble solids content in G-9 (15.7), and the highest in G-5 (18.88). The genotypes tested in the present research had somewhat lower soluble solids contents in comparison to the findings of the above author. Fruit weight was lowest in GG3 (61.49±4.45 g), followed by GG2 (66.35±4.90 g) and GG1 (68.08±5.17 g), and highest in GG4, GG5 and the control cv. 'Roxana'. Fruit weights of all genotypes were greater than the average (60 g). Milošević *et al*. (2009) obtained somewhat different values for fruit weight, ranging between 41.34 g in G-5 to 81.5 g in G-1, possibly resulting from either different climatic and other conditions during the research or different genotypes analysed in this study. Similar results on greater fruit size in selected genotypes than in 'Hungarian Best' were obtained by Licznar-Małańczuk and Sosna (2005). Stone weight in the tested genotypes as an important trait for cultivar identification and classification varied from 3.80±0.25 g in GG3 to 4.37±0.22 g in GG2. When compared with 'Roxana', stone weight was lower in two genotypes and higher in three. The flesh to stone ratio ranged from 93.41 % in GG2 to 94.79 % in 'Roxana'. The present results on stone weight and flesh/stone ratio are similar to those of Milošević *et al*. (2009).

Conclusions

In comparison to the control cultivar, all apricot genotypes began to flower 2 to 3 days earlier and exhibited a similar course and abundance of flowering. The beginning and end of ripening was 5 to 6 days earlier than in the control ('Roxana'). As regards leaf characteristics, leaf dimensions were greater in GG1 and GG2 than in the control. All genotypes had shorter petioles and fewer glands. When analysing fruit dimensions and fruit weight, fruit size was found to be similar in GG5 to that of 'Roxana', followed by GG$, whereas the other genotypes had smaller dimensions. Soluble solids content was highest in GG1. This trait exhibited no significant differences between the genotypes and 'Roxana'. Flesh to stone ratio in the tested genotypes was not significantly different from 'Roxana'. Overall, the largest number of positive traits was exhibited GG5 and GG4, which can serve not only as experimental material in further research, but also for orchard establishment.

Acknowledgement

This study is part of Project Ref. No. TR 31064 ("Creation and Maintenance of the Genetic Potential of Continental Fruit Crops") financially supported by the Ministry of Education, Science and Technological Development of the Republic of Serbia. Abstract

During a two-year period, two varieties of spring malting barley, Mile and Marko, were studied, which were created at the Institute of Field and Vegetable Crops in Novi Sad.Grain yield, weight of 1000 grains and hectoliter mass of grains were examined. The experiment was carried out in the vicinity of Kruševac according to the plan of a random block system in four repetitions, and the size of the base parcel was $5m^2$.The sowing standard was 400 germinable kernels/m^2. The experiment includes the fertilization factor with growing nitrogen doses N_0, N_{80}, N_{100}, N_{120}. At variants with a nitrogen dose, another 90 $kgha^{-1}$of P_2O_5 and K_2O were used. Sowing density and applied nitrogen doses are two extremely important factors in the production technology of spring malting barley. In the interaction with the genotype of the variety and different soil factors as well as climatic factors, it contributes decisively to obtaining high yields of good grain quality.The aim of this research is to examine the influence of increased nitrogen doses in mineral nutrition on fertility parameters and grain quality of spring malting barley. The achieved results of the study show that the use of nitrogen had a positive effect on fertility parameters and grain quality of spring malting barley in all varieties and at both varieties.Using a higher nitrogen dose, a somewhat larger mass of 1000 grains was found in the fertilization variant of 100 kg ha^{-1}N per average for the examined two-year period, while the hectolitre mass was somewhat higher in the case of the fertilizer variant of 80 kg ha^{-1}N in the Mile variety as well as the higher yield of grain in relation to the variety Marko.The different reaction of the tested varieties on the application of mineral fertilizers is the result of their varietal specificity.

Keywords:*mass of 1000 grains, spring barley, yield, variety*

Introduction

Barley is cultivated at around 49, 43 million hectares in the world, with an annual production of about 144, 49 million tons and an average yield of 2.9 t ha^{-1} (FAOSTAT 2015). Barley (*Hordeum vulgare* L.) is a very important cereal, which occupies the fourth place behind wheat, corn and rice by sown areas (Bengtsson, 1992; Langridge and Barr, 2003; Zečević*et al*., 2011; Awika, 2016).Barley is grown around the world and is used as an important component in the production of beer and malt; it is also an important and quality component in the nutrition of domestic animals, while it is partially used in human nutrition. In Serbia, for the last five years, about 50% of barley production has been used for animal feed production, and 50% in the brewing industry (Kandić, 2015).In comparison to the older varieties of barley that were in the production in the eighties, newer varieties are characterized by good technological quality, better resistance to lodging and disease, shorter stem and more efficient use of assimilatives (Bratković*et al*., 2014; Đekić*et al*., 2010;). The weight of 1000 grains in brewer barley ranges from 68 to 75 kg ha^{-1} (Paunović*et al*., 2006).

The yield and quality of the grain is greatly influenced by the balanced mineral nutrition, which is adapted to the natural fertility of the soil and the needs of the barley (Glamočlija*etal*.,

1998). The influence of mineral nutrition on the characteristics of beer barley originates both from the quantity of individual nutrients and from their relationship, as well as from the way they are introduced into the soil and the time of their application(Stankovi*et al.*, 2000).Unlike other stubble cereals, barley has higher demands on mineral nutrition, with a particular influence of nitrogen on the yield and quality of barley grains (Knežević, 2005). Nitrogen is the element that has the greatest influence on the vegetative development of the plant, its photosynthetic capacity and yield (Evans, 1983; Knežević, 2014). It is an integral part of many important cellular compounds, such as amino acids, proteins (enzymes and structural proteins), nucleic acids (DNA and RNA), adenosine triphosphate (ATP), chlorophyll and some phytohormones (auxin and cytokinin) (Santiago-Antonio *et al*., 2014).Since barley plants adopt nitrogen almost to the very end of vegetation, its excessive concentration in soil can leads to great adoption by the plant, and consequently to an increase in protein content in grains (Paunović and Madić, 2011). The content of protein in barley grains is of the highest importance from the standpoint in the brewing industry, and their content should range from 8.5 to 12.5% (Gali and Brown, 2000). In spite of the direct influence of nitrogen on the increase in protein content in grains, its indirect influence is also importantconcerning thelodging of plants (Perić, 1982, 1986; Paunović, 2001). Therefore, it is very important to know the properties of the resistance of the variety to lodging.

Spring barley occupies much larger areas in most European countries than winter barley.

The production of beer barley with high yield of grain and appropriate quality is possible only by choosing a quality assortment with suitable growing conditions and appropriate production technology. In the two-year period at a field experiment in the village of Globoder near Kruševac, two Novi Sad varieties of spring barley were examined in order to determine the selection of the best varieties for the production conditions in Serbia.

Material and Methods

During a two-year period, two varieties of spring malting barley, Mile and Marko, were studied, which were created at the Institute of Field and Vegetable Crops in Novi Sad.Grain yield, 1000 grain weight and hectolitre grain weight of two varieties of spring malting barley were examined.An experiment was set in the vicinity of Kruševac in the region of the village of Globoder.The size of the base parcel was 5.0 m^2 in four repetitions per split-plot method with a random schedule of treatment. The sowing was carried out manually in rows with 400 germinable kernels/m^2.The experiment includes the fertilization factor with growing nitrogen doses N_0, N_{80}, N_{100}, N_{120}. At variants with a nitrogen dose, another 90 $kgha^{-1}$ of P_2O_5 and K_2O were used.The following properties were analyzed: grain yield, mass of 1000 grains and hectolitre mass. Standard production technology was used in the experiment.Barley harvest was done at a full maturity stage with grain yield measured and corrected to 14% moisture. From the qualitative characteristics of the grains, the hectolitre mass of the grain was made, measured on the hectolitre scale and the weight of 1000 grains.

The land on which the experiment was performed by type is alluvial (fluvisol). The subtype of leached fluvisol represents a somewhat older alluvial soil, in fact, transitional formation from carbonate fluvisol to a poorly developed meadow black soil.Although it does not contain $CaCO_3$ in the arable horizon, the derived fluvisol has fairly favorable chemical properties. The land is medially provided by humus (3.25%), pH in H_2O = 6.50 in KCl = 5.72, while the total nitrogen content is 0.23. The content of the easily accessible phosphorus was 17 mg of 100 g^{-1} soil, the content of easily accessible potassium was 20 mg of 100 g^{-1} of the soil.

The area of Kruševac is bounded by the coordinates of 43˚22'29 "and 43˚42'17" north latitude, and 21˚9 'and 21˚34'8 "of the eastern latitude. The climate is moderately continental.

Barley has relatively low heat requirements. The total temperature sum of 1750˚ C (Miržinski*et al*., 1966) is required for the development of spring barley. The years in which

the meteorological conditions were tested differed from the multiyear average characteristic for this area (Table 1).The average air temperature was higher by 1.3˚C in 2014 compared to the perennial average.The period February, March, April was marked by a much warmer time than the perennial annual average, and the thermal conditions for emergence in 2014 were favourable.The precipitation was in smaller quantities and the sprouting was uneven and inconsistent. The relatively favorable thermal regime of plants in May was accompanied by higher precipitation quantities.Elevated temperatures accelerated the vegetation cycle, which resulted in accelerated barley ripening and earlier harvesting. The average amount of precipitation during the vegetation period of spring barley (February - July) was 595.9 mm, while the perennial average was 320.5 mm.A critical period in terms of demand for water is also in the filling phase of the grain. Spring barley is the most sensitive to reducing soil moisture in the six-leaf phase.

In 2015, the average air temperature was higher by 0.8˚ C compared to the perennial average.The first three months of this year were marked by a warmer time compared to the perennial average. The precipitation was in sufficient quantities and the sprouting was even and uniform unlike in 2014.The relatively favorable heat regime in the remaining four months of the vegetation period in this year of testing was followed by a lower amount of precipitation compared to the same period in 2014, which did not interfere with further development of life processes in spring malting barley in further stages of development in the year of testing.The average amount of precipitation for the February-July vegetation period in this year was 379.0 mm compared to the perennial precipitation average of 320.5 mm, which is significantly less compared to the first year of testing.

Based on data on mean monthly air temperatures and precipitation amounts during the study, we conclude that the weather conditions varied by year, especially in terms of the amount and distribution of precipitation and that they were somewhat more unfavorable in 2014.

Table 1. Average monthly temperature and precipitation sum

year	Months						Average

Results and Discussion

Numerous experiments on the optimization of the application of the nitrogen fertilizers for achieving high yields in the world and in our country are quite contradictory. Thus, Ruza et al., (2011). in the pedologic and climatic conditions of Lithuania determines the optimum yield increase of 26.7% using 90 kg h^{-1} N; further increase in the application of N was not accompanied by an increase in yield. According to Medić et al. (2017) on acidic soils the yield of barley is significantly influenced by mineral nutrition applied in combination with calcification of soil or genetics, i. e. cultivated variety. These results and many other point to the complex interactions of climatic-pedological conditions, genetics, and applied mineral nitrogen in the production of barley.

In our tests the influence of 100 kg h^{-1} N during the two years in the investigated varieties proved to be optimal in the given soil-climatic conditions (Table 2). The influence of the

optimum application of N (120 kg h^{-1}) on the tested variety Marko in climatic conditions during 2014 influenced the increase in the yield for 2050 kg h^{-1} compared to the control(N_0 kg h^{-1}). The achieved yield increase was 105% compared to the control. During the same year (2014) and the same optimal treatment (120 kg h^{-1}) with the Mile variety, an increase of 1530 kg h^{-1} was achieved, which increased the yield by 66% compared to the control (N_0 kg h^{-1}). In contrast, with Mile variety in the climatic conditions that were present in 2015 when the optimal application of N (120 kg h^{-1}) was realized, there was an increase in the yield of 1900 kg h^{-1} and with Marko variety 1590 kg h^{-1}, indicating all the complexity of the interaction of the variety x environment, or selection of a variety for certain climatic conditions.

Table 2. Yield (kg h^{-1}) by varieties, fertilization variants and years

variety	Year	Fertilization variants

A-variety, B-fertilizer dose, C-the year of study

The influence of the variety, the dose of nitrogen application in the two years studied, influenced the absolute mass of 1000 grains by 4.96 g. (variety Marko, application of N 80 kg h^{-1}, 2015 36,07 g and maximum value of 41,03 g on the same variety without application of N during 2014). However, the impact of the individual influence of the variety, the application of mineral nitrogen and the year influenced little to the absolute weight of 1000 grains (Table 3).

Table 3. Absolute mass of 1000 grains (g) by varieties, fertilization variants and years

Variety	year	Fertilization variants				
		0	80	100	120	average
Mile	2014	39.05	39.00	38.02	38.09	38.54
	2015	39.25	39.22	41.06	39.04	39.64

0,01	1,38	1,38	2,76	0,97	1,95	1,95	3,90

A-variety, B-dose of fertilizer, C-the year of studyest

For all variants of the application of nitrogen fertilizer and the year Mile variety had a higher hectolitre mass by 0.82 kg hl^{-1}(Table 4). In general, thehectolitre mass by 0.82 kg hl^{-1} , depending on the variety, fertilization variants during the two years varied by 6.05 kg hl^{-1}

(variety Mile, application of N 100 kg h^{-1}, in 2015 68.83 kg $hl^{-1}$and the maximum value of 74.85 kg hl^{-1}on the same variety with the application of 80 kg h^{-1} of N during 2014).

Table 4. Hectolitre mass (kg hl^{-1}) by varieties, fertilization variants and years

Variety	year	Fertilization variants				
		0	80	100	120	average
Mile	2014	73,01	74,85	72,06	73,05	73,24
	2015	70,60	73,60	68,83	72,16	71,30
	Average	71,81	74,23	70,45	72,61	72,28

0,01	1,32	1,32	2,64	0,93	1,87	1,87	3,74

A-variety, B-dose of fertilizer, C-the year of study

Using the simple correlation coefficients significant ($p \leq 0.05$) negative correlation between yield and absolute mass of 1000 grains (r=-0.662) was found as well as between the absolute mass of 1000 grains and the hectolitre mass in Mile variety. There was no significant ($p \geq 0.05$) interrelation between the traits found in Marko variety (Table 5).

Table 5. Correlation coefficients between tested properties (n=10)

Variety						
	Mile			Marko		
property	I	II	III	I	II	III
yield (kg h^{-1}) I	-	-0.662*	0.077 NS	-	-0.102 NS	0.422 NS
Absolute mass of 1000 grains (g) II		-	-0.662*		-	0.170 NS
Hectolitre mass (kg hl^{-1}) III			-			-

Statistical significance levels: *$p \leq 0.05$, NS – not significant ($p \geq 0.05$).

Conclusions

The investigated varieties behaved differently according to the climatic conditions in which the yield was formed, as well as for the interdependence of grain yield and quality parameters: the absolute mass of 1000 grains and the hectolitre mass. On the basis of the coefficient of correlation, it was established that significant interdependence was not found in variety Marko, while in variety Mile significant ($p \leq 0.05$) negative interdependence was found between the yield and the absolute mass (r=-0.662) and between the absolute mass of 1000 grains and the hectolitre mass (r=-0.648).This points to all the complexity of choosing a variety to achieve maximum yields and grain quality.

In given pedological climatic conditions, the application of nitrogen of 100 kg h^{-1} clearly proved to be optimal for both tested varieties and during both years.

EFFECTS OF ZEOLITE ON GERMINATION OF SOYA BEAN SEED AND ITS USE AS A SUBSTRATE

Jasna KOJIĆ*, Nebojša RADOSAVLJEVIĆ, Tanja PETROVIĆ, Marija MILIVOJEVIĆ

Abstract

Zeolite is a mineral of volcanic origin with negatively charged crystalline sieve that, according to many studies, has the ability to exchange ions. Mechanical processing - grinding of zeolite results in the increase of the particle surfaces and thereby its ability to adsorb heavy metals, mycotoxins, positively charged ions of sodium, potassium, nitrogen. The aim of the present study was to determine the effect of natural zeolite on seedlings and their development, as well as on total soya bean seed germination under laboratory conditions. The use of zeolite in the combination with soil and sand, as methods for seed germination, was observed in the study. The test was conducted on three samples of soya bean seeds at the Seed Testing Laboratory of the Maize Research Institute, Zemun Polje. Particles (0.3-1 mm) of natural zeolite, mixed with soil and sand in the concentration of 1% and 3%, were used in the study. The soil type was degraded chernozem taken form the ploughing layer of the maize field and prepared according to the standard procedure: 4x100 seeds of soya bean were tested by the methods filter paper + soil, filter paper + sand (standard), filter paper + soil + zeolite (1% and 3% weight percentages) and filter paper + sand + zeolite (1% and 3% weight percentages). Seeds were germinated in the germination cabinet at the alternating temperature of 20<=>30^{o}C (16 h : 8 h / light : dark photoperiod) for 8 days. The use of zeolite increased germination of soya bean seeds, while different concentrations of zeolite did not significantly increase germination.

Key words: *zeolite substrate, germination of soya bean seeds*

Introduction

Zeolite is a mineral of volcanic origin found in 1756. This mineral has the capacity to intensively lose water during heating, due to which was named *zeolite* from the Greek language zéō – meaning to boil and lithos – meaning stone, Polat et al. (2004). There are over 50 types of naturally occurring zeolites. The most important and most observed is clinoptilolite, which has a three-dimensional structure with the ability to exchange ions, due to which it is a good absorbent. Due to electric charge of the aluminium-silicate surface, clinoptilolite is known as a "molecular sieve", Ramôa (1993) and is used in industry, agriculture, environmental protection, medicine, decontamination in the military industry.

The use of zeolite in agriculture began in 1960 on farms in Japan. Japanese farmers used to apply zeolites for years to control the soil moisture content, improve the soil structure and ph. Mineral zeolite possesses three main properties of great importance in agriculture: high capacity of cation exchange, high water holding capacity and high absorption capacity, Mumpton (1999). Alongside water, nutrients are also retained in the zone of the root system, so that plants can use them when needed.

There are many studies dealing with the effects of zeolites on seedlings, the development of shoots and roots. Trinchera et al. (2009) have observed effects of various zeolite granular sizes on maize seedlings. It was established that the application of granular and micronised zeolites in the substrate favoured the occurrence of secondary roots and root hairs. On the other hand, the use of micronised zeolite positively affected the development of maize shoots. The highest increase in the length to weight ratio in primary roots of maize has been

obtained by the treatment with micronised clinoptilolit in the amount of 0.1%, while the lowest increase was gained by the treatment with granular clinoptilolit, which indicates the effect of different granular sizes of clinoptilolit on the maize root.

Furthermore, the effect of zeolite on plants by its activity and by the combinations of various substrates, has been also studied. Yilmaz et al. (2014) have concluded that the zeolite, turf and perlite mixtures improved the cucumber seedling quality, hence zeolite can be successfully used in the seedling production.

Oilseed rape seedlings growing under stress conditions of drought without zeolites have a less dry weight and a lower total germination percentage. Moreover, the ratio of above ground parts to root is less favourable and therefore the chances to survive stress conditions of drought are smaller. As a result of this, quality and quantity of produced seeds have been decreased, Armandpisheh et al. (2009).

Khan et al. (2009) have observed effects of zeolites on soya bean seeds and established the increase of seed quality and germination when zeolite was applied at the rate of 1 and 2%. The zeolite addition to soya bean crops increased germination and vigour, and decreased the level of seed infection caused by *Phomopsis* sp.

Material and methods

The study was performed in the Seed Testing Laboratory of the Maize Research Institute, Zemun Polje on seeds of three soya bean cultivars. Zeolite provided by the company "Zeomedik", Altina-Zemun, was of the following composition: clinoptilolit - 94%, quartz - 4% and phlogopite (mica) - 2%. Granulation of the used zeolite ranged from 0.3 to 1mm.

The effects of zeolite in the mixture with the soil in the mass concentration of 1-3% and quartz sand in the same concentrations were observed. Both substrates were combined with the filter paper. Soil and sand without zeolite, also combined with the filter paper, served as control variants.

Prior to their use, all substrate were tested according to the ISTA Handbook of Seedling Evaluation (2013). The used soil was degraded chernozem collected from a maize field with the following parameters: pH - 7.5, moisture - 17.9%, moisture capacity - 48%. The sand fraction size was 2.6, moisture 0.033%, pH 7.5, moisture capacity 29%. The properties of the filter paper were as follow: weight - 110 g, pH 7.5, moisture 4.7 and moisture capacity 37%. *Festuca rubra* seeds, susceptible to substrate toxicity, were germinated and it was determined that soil, sand and filter paper did not contain toxic substance and that they met requirements of the standard.

A total of 4x100 seeds were studied by their placing on filter paper + soil, filter paper + soil + 1% zeolite and paper + soil + 3% zeolite, filter paper + sand, filter paper + sand + 1% zeolite and filter paper + sand + 3% zeolite. Seeds were germinated in the germination cabinet at the alternating temperature of 20<=>30^{o}C under light: dark photoperiod of 8 h : 16 h. The final count was read after 8 days, International Seed Testing Association (2017). The obtained values were expressed in the percentage participation of normal seedlings.

Results were statistically processed by a computer program MSTAT. The two factorial analysis of variance and the least significant difference (LSD) test were applied, Hadživuković (1991).

Results and discussion

The analysis of variance showed the statistically significant differences in obtained values of total seed germination and the applied test method (factor A) and in tested cultivar seeds (factor B). Total seed germination did not significantly differ over replications and interactions between observed factors (Table 1).

Table 1. Statistical significance of effects of observed factors on total seed germination

Factor	Degree of freedom (DF)	Mean squares (MS)	F value
Replication	3	33.037	0.9044^{ns}
Factor A (method)	5	407.689	11.1612^{**}
Factor B (cultivars)	2	561.556	15.3736^{**}
AB	10	21.956	0.6011^{ns}
Error	51	36.527	

ns – not significant; ** - significant at the 0.01% level

Table 2 shows total seed germination over methods and cultivars expressed in % – the soil /filter paper/zeolite (1% and 3%) combination. The lowest, i.e. highest value of total seed germination for all three methods was in the third, i.e. the first cultivar, respectively.
The addition of 1% zeolite increased total seed germination by 7-9% in relation to the control variant. The number of abnormal seedlings was decreased by 5-7%, while the percentage of dead seeds remained approximately the same. Moreover, the addition of 3% zeolite significantly increased total seed germination in comparison to the control method. Total germination increased by 11-13% over cultivars on the account of abnormal seedlings. The percentage of dead seeds decreased insignificantly (by 2-3%).
The zeolite concentration of 3% resulted in the increase of total germination, similar as with the concentration of 1%. The comparison of zeolite concentrations shows that seed germination was higher by 2-6% when the higher concentration of zeolite was applied.
In the course of the germination evaluation it was determined that the soil, with or without zeolite, was not suitable substrate for soya bean seed germination. Tender soya bean shoots penetrate soil with difficulty, therefore seedlings in the middle of the role are brittle, smaller and discoloured, which resulted in breakage of hypocotyls. Unlike hypocotyls, the root was strong and well developed in normal seedlings. Due to the zeolite property to hold water, the soil was compact, which made the extraction and the evaluation of seedlings more difficult.

Table 2. Values of total seed germination over methods in % – soil/zeolite combination

Cultivar	Control FP + soil			Method FP + soil + 1% zeolite			Method FP + soil + 3% zeolite		
	Normal seedlings	Abnormal seedlings	Dead seeds	Normal seedlings	Abnormal seedlings	Dead seeds	Normal seedlings	Abnormal seedlings	Dead seeds
1	61	24	15	68	19	13	74	14	12
2	63	23	14	72	16	12	73	15	12
3	56	27	17	63	20	17	65	21	14

Table 3 shows total seed germination over methods and cultivars expressed in % – the soil /filter paper/zeolite (1% and 3%) combination. The lowest, i.e. highest value of total seed germination for all three methods was in the third, i.e. the first cultivar, respectively.
The addition of 1% zeolite increased total seed germination by 3-9% in relation to the control variant. The number of abnormal seedlings was decreased by 4-9%, while the percentage of dead seeds remained approximately the same. The addition of 3% zeolite increased total seed germination by 6-8% in comparison to the control method. The percentage of dead seeds decreased insignificantly (by 1-2%).
The comparison of zeolite concentrations shows that total seed germination was higher by 2-4% when higher concentrations of zeolite were applied.
In the course of the germination evaluation it was observed that sand was a better substrate for soya bean seed germination than soil. The use of sand as a substrate in all three methods (with

different zeolite concentrations, or without zeolite) resulted in robust seedlings with the strong root system and well developed hypocotyls. Sand in the combination with zeolite provided a loosened germination medium, which enabled the easier evaluation and extraction of well developed seedlings.

Table 3. Values of total seed germination over methods in % – sand/zeolite combination

Cultivar	Control FP + sand			Method FP + sand + 1% zeolite			Method FP + sand + 3% zeolite		
	Normal seedlings	Abnormal seedlings	Dead seeds	Normal seedlings	Abnormal seedlings	Dead seeds	Normal seedlings	Abnormal seedlings	Dead seeds
1	74	18	6	83	9	8	81	15	4
2	73	19	8	77	12	11	79	12	9
3	64	17	19	67	13	20	71	12	17

The analysis of results by the LSD test for the interactions among cultivars shows the significant difference in total seed germination. The lowest difference was in the cultivar 3, while there were no significant differences in remaining cultivars (Table 4.).
The highest and the lowest values of total seed germination were obtained by the methods: sand + filter paper + 3% zeolite and soil + filter paper, respectively. A statistically significant difference was achieved by the method 6, with the highest total seed germination and by the method 1 with the lowest total seed germination. There were no statistically significant differences in remaining methods (Table 5).

Table 4. LSD test for observed cultivars

Cultivar	Total germination
1	73.17^{A}
2	72.17^{A}
3	64.33^{B}

Table 5. LSD test for applied methods

Ordinal number	Test methods	Total germination
1	Soil + filter paper	60.00^{D}
2	Soil + filter paper + 1% zeolite	67.33^{C}
3	Soil + filter paper + 3% zeolite	70.50^{BC}
4	Sand + filter paper	70.33^{C}
5	Sand + filter paper + 1% zeolite	75.33^{AB}
6	Sand + filter paper + 3% zeolite	75.83^{A}

Conclusion

According to gained results it can be concluded that sand is a better substrate than soil for soya bean seed germination. This was confirmed by the comparison of results of total germination of control methods in soil and in sand. It was established that the best substrate to germinate soya bean seeds is sand in the combination with 3 % zeolite. The highest total germination was achieved by this method, and the presence of zeolite provided a loosened and sufficiently wet medium that provided easer extraction of seedlings. In the course of the germination evaluation, seedlings were strong with well developed roots and hypocotyls.
Soil in the combination with zeolite was not such a good substrate, because zeolite bound water and soil became sticky and cloddy, so extraction of brittle and breakable seedlings was

difficult. On the other hand, the increase in the zeolite percentage in the combination with soil improved total seed germination.

Results obtained on total seed germination showed that the application of both lower and higher concentrations of zeolite significantly affected its increase. The comparison of results gained on concentrations shows that better effects were achieved by the higher zeolite concentration. According to these results the recommendation would be to apply 3% zeolite with seed in the sowing season.

Sand is used for germination tests of soya bean seeds in the Seed Testing Laboratory. The substrate sand + zeolite could be applied in poor quality soya bean seed lots in order to obtain maximum seed germination necessary for seed trade.

Abstract

The production and utilization of intercropped, complementary legume : cereal bi-crops as ruminant feeds is beneficial for many reasons. The nitrogen fixation by the legume benefits the cereals and decreasing the need for N fertilization. In turn, the cereal supports the legume, thereby preventing the lodging that typifies pure stands of mature forage pea. The investigations were carried out to evaluate the quality of oat (*Avena sativa* L.) and pea (*Pisum sativum* L.) in pure stands as well as in mixtures of 75:25, 50:50 and 25:75 ratios at the Institute for forage crops to address the problem of nutritious green forages for livestock in the region. The samples were harvested at the beginning of pea flowering – 10% of flowering and at the forming green seeds in 2/3 pea pods. Green forage samples were assayed for CP (Crude Protein), Crude Ash, Ether Extract, NDF (Neutral detergent Fiber), ADF (Acid Detergent Fiber), Hemicellullose, ADL (Acid Detergent Lignin) and IVDMD (*in vitro* Dry Matter Digestibility). Oat:pea mixtures produced higher crude protein content than oat pure stand. 75:25, 50:50 and 25:75 oat : pea mixtures resulted in 46.4%, 57.0% and 80.5% higher crude protein content than oat pure stand, respectively. The highest forage quality parameters were achieved when pea was grown as a monoculture or when at a high proportion (75%) in mixture. The results showed that mixture of pea and oat at the 75:25 seeding ratio was obtained the highest forage quality.

Keywords: oat*:pea mixtures, forage quality, dry matter digestibility*

Introduction

Bi-crops of various grain legumes and cereals have received much attention because of their high yields (Salawu et al., 2001). In particular, bi-crops with pea varieties or mixtures with high grain to straw ratios are considered to have a good balance of energy and protein contents (Anil et al., 1998). Legumes are rich in terms of protein concentration, whereas cereals have higher carbohydrate contents, and cereal benefit from the nitrogen fixed by legumes when they are grown together. Several researches reported that annual legume-cereal mixtures resulted in high yields and high nutritional quality as compared with cereal alone (Yolcu et al., 2009; Balabanli et al., 2010; Kocer et al., 2012). The goal of most dairy farmers is to use the available land to produce cheaper but high quality feed with adequate protein content for lactating cows in order to maximize milk yield (McKenzie and Spaner, 2002). From the nutritional point of view, pea-oat intercrops offer the possibility of reduced importation of protein concentrates in ruminant diets as well as increased value of harvested product because of increased protein content.

Pea forages have higher crude protein and *in vitro* digestible organic matter in DM, and lower neutral detergent fiber (NDF) and acid detergent fiber (ADF) than wheat (Salawu et al., 2001), and higher CP contents than oat (Faulkner, 1985). However, adding pea to wheat, oat or barley increases forage CP concentration and decreases NDF and ADF (Salawu et al., 2001). Mustafa and Seguin (2004) found that whole-crop pea silage has similar forage yields, but higher CP and lower NDF contents than pea-cereal silages and that the *in vitro* DM

digestibility of pea silage is higher than that of pea-cereal mixtures at earlier harvest, but the difference is reduced at later harvest (Mustafa and Seguin, 2004).
However, it can be difficult to determine the best time to harvest whole crop forages to optimise their nutritive value without compromising yield. The quality of grain legumes (e. g. peas), whole crop cereals and their bi-crops, do not decline with age in the same manner as grasses and legumes, because of the additional influence of the grain and pod yields (Salawu et al., 2001). This makes it more difficult to determine the appropriate harvest time for these crops to use indairy herd feeds.
The main aim of the present study was to determinate the nutritive value and the *in vitro* dry matter digestibility of oat and pea sown in pure crop and in bi-crop mixtures depending on different seeding rate and harvested at different time.

Materials and methods

The experiment was designed with three replications according to a randomized complete block. Experiment was established in autumn in 2012, on October the 20th and the samples were taken in spring in 2013. Pea and oat were grown in binary mixtures at the experimental field of Institute for forage crops, Kruševac – Serbia (21º19´35´´ E, 43º34´58´´ N). The pea and oat were tested at five different mixture rates: 100% pea + 0% oat; 0% pea + 100% oat; 25% pea + 75% oat; 50% pea + 50% oat and 75% pea + 25% oat. All mixtures were sown on plots of 20 m^2. Initial soil test from 0-30 cm soil depth before the trial commenced showed 0.16% N, 4.9 mg P_2O_5 / 100 g of soil, 23.1 mg K_2O / 100 g of soil, 3.5% organic matter and a pH of 5.7 in N KCl. One level of fertilizer was applied, 300 kg ha^{-1} NPK (15:15:15) before the seeding. Plant samples were taken in spring 2013, at the beginning of pea flowering – 10% of flowering and at the forming green seeds in 2/3 pea pods.
Standard procedures described by the AOAC (1990) were used to determine ash (AOAC, 942.05), crude protein (CP; AOAC 984.13) and ether extract (EE, AOAC 954.02). NDF assayed with heat stable α-amylase (aNDF), acid detergent fiber (ADF), hemicellulose (HCL) and lignin content were determined according to Van Soest et al. (1991). Two stage pepsin-cellulase method was used for *in vitro* DM digestibility (De Boevar et al., 1986).
The experimental data were analyzed by a two-way analysis of variance for silage samples using a model that accounted for the main effects of pea:oat mixtures and time of harvest. Effects were considered different based on significant ($p< 0.05$) F ratio. The significance of differences between arithmetic means was tested by LSD test (STATISTICA 6, Stat. Soft. 2006).

Results and discussion

An analysis of variance found statistically significant differences among cutting stages for investigated forage quality parameters (Table 1). Results of this study showed that CP, ash, ADF and DMD decreased, whereas EE, NDF, hemicellullose and ADL contents increased with advancing plant growth and development. The increasing NDF and ADL content with plant development affected decreasing of DMD from 706.3 g kg^{-1} DM to 600.1 g kg^{-1} DM. With advancing the plant maturity CP content decreased by 9.2%, whereas NDF and ADL content increased by 7.9% and 11.5%, respectively. Many researchers reported similar rasults (Uzun and Asik, 2012; Turk et al., 2007; Tan and Serin, 1996). The forage quality of grasses and legumes declines with age due to reductions in the leaf – to – stem ratio in conjuction with a decline in the stem component nutritive value. Therefore, the strategy for obtaining good quality forage is to harvest when the leaf – to – stem ratio is high. In contrast, the quality of grain legumes (e. g. peas), whole crop cereals and their bi-crops do not decline with age in the same manner as grasses and legumes, because of the additional influence of the grain and pod yields (Salawu et al., 2001).

A_1- beginning of pea flowering – 10% of flowering; A_2- forming green seeds in 2/3 pea pods. B_1-100% pea + 0% oat; B_2-0% pea + 100% oat; B_3-25% pea + 75% oat; B_4-50% pea + 50% oat; B_5-75% pea + 25% oat. CP-Crude Protein; EE-Ether Extract; ADF-Acid Detergent Fiber; aNDF-Neutral Detergent Fiber; HCL-Hemicellulose; ADL- Acid Detergent Lignin; DMD-Dry Matter Digestibility. Different letters denote significantly different means ($P< 0.05$).

Åman and Graham (1987) found that in pea plants the most dramatic changes in the distribution of chemical constituents occur during the pea filling process, a rapid exponential phase of pea growth. The same authors indicated that nutrients, especially carbohydrates and protein are translocated from the vegetative parts of the plant to the pea grains, while the leaves and stems gain cellulose, hemicellulose and lignin. They also concluded that the gross chemical composition of the whole crop remains remarkably constant, with the exception of the transformation of soluble sugars to starch and the increased content of cell walls. Trevino et al. (1987) pointed out to the fact that in forages harvested at early pod fill stage the leaf component constitutes the largest part of the total plant dry weight, but at later harvest the fully developed peas constitute around half of the whole crop (Åman and Graham, 1987), and after an initial increase the CP remains relatively uniform, as does the lignin content. On the another hand, Jaster et al. (1985) found that in pea-oat bi-crop forage the CP content declines during maturity, but the DM, CP, starch, NDF content and *in vitro* digestible organic matter of pea forages increase with maturity.

Crude protein content of forage is one of the most important criteria for forage quality evaluation (Assefa and Ledin, 2001). In all mixtures, the CP content increased as field pea

seeding proportion increased (P< 0.05), (Table 1). Monoculture field pea had the highest CP content (204.3 g kg^{-1} DM), followed by the mixture of pea with oat (75 : 25) (179.8 g kg^{-1} DM). Monoculture oat had the lowest content of CP (99.6 g kg^{-1} DM) and pea-oat mixtures (25 : 75, 50 : 50 and 75 : 25) had 46.4%, 57.0% and 80.5% more CP respectively than monoculture oat.

The ash and EE were also affected by composition of pea-oat mixtures. The highest ash and EE contents were determined in pure oat (103.7 g kg^{-1} DM and 30.1 g kg^{-1} DM, respectively). Increasing pea proportion in the mixtures affected decreasing the ash content, but EE content did not changed in the same way (Table 1).

The lowest ADF content was determined in the pure pea (357.4 g kg^{-1} DM) and with increasing pea seeding rate in the pea-oat mixtures ADF content increased from 395.7 g kg^{-1} DM (25 : 75 pea-oat mixture) to 406.1 g kg^{-1} DM (50 : 50 pea-oat mixture). These ADF values did not differ significantly from pure oat ADF content (400.6 g kg^{-1} DM). In all pea-oat mixtures the content of ADF was higher than in pure oat, and according to the pea seeding rate in the mixture was the lowest in 75 : 25 pea-oat mixture (372.5 g kg^{-1} DM). The highest NDF content was determined in pure oat (602.9 g kg^{-1} DM), but with decreasing seeding rate of oat in the mixture NDF content increased from 537.5 g kg^{-1} DM in 25 : 75 pea-oat mixture to 549.4 g kg^{-1} DM in 50 : 50 pea-oat mixture. The NDF content in the 75 : 25 pea-oat mixture was lower than NDF content in pure oat. Content of hemicellulose changed in the same way as NDF with increasing pea seeding rate in pea-oat mixture (Table 1).

Kocer and Albayrak (2012) pointed out that ADF and NDF contents increased as the pea seeding ratio decreased in mixtures. These authors also indicated that monoculture pea had the lowest values of ADF (25.81%) and NDF (38.27%) whereas the highest ADF and NDF values were observed in the monoculture of oat (34.61% and 59.12%). Van Soest (1996) indicated that under similar growth conditions legumes have lower NDF and ADF than cereals, wich are in agreement with the present study.

Results of the present study showed that the lowest ADL content was determined in pure pea (66.3 g kg^{-1} DM), and the highest ADL content was in pure oat (75.7 g kg^{-1} DM) and in 25 : 75 pea-oat mixture (75.9 g kg^{-1} DM). With increasing pea seeding ratio in pea-oat mixtures, content of ADL decreased from 75.9 g kg^{-1} DM to 69.6 g kg^{-1} DM. DMD was significantly different among the experimental treatments, with the exception of 25 : 75 and 50 : 50 pea-oat mixtures. The highest DMD was recorded in pure pea (744.9 g kg^{-1} DM) and the lowest in pure oat (562.9 g kg^{-1} DM). DMD decreased in mixtures with increasing pea seeding rate from 25:75 to 50:50 pea-oat mixture. The reason could be found in the fact that 50 : 50 pea-oat mixture had high level of NDF and ADF content.

Conclusions

According to the data obtained from this research work, it was realized that pea and oat can be planted succesfully for herbage and hay production. Forage quality of pea-oat mixtures was generally affected by stage of plant development and seeding rate of pea and oat. Cultivating pea and oat in mixtures were found to be advantageous in increasing forage quality. Growing oat in a mixture with pea significantly increased forage quality – CP and DDM, compared to pure oat. This confirms that growing leguminous forages like pea in a mixture with oat addresses dietary advantages especially in terms of CP and DDM on ruminal animal production. The lowest quality was deterrmined in 50 : 50 pea-oat mixture because this mixture had the highest NDF and ADF contents and consequently the lowest DDM.

Abstract

Various groups of microorganisms live in the soil: aminoheterotrophs, aminoautotrophs, oligonitrophilic bacteria, cellulolizators, *Azotobacter* sp., actinomycetes, fungi, sporogenic bacteria and others. The mentioned groups of microorganisms have a precisely determined and irreplaceable role in the processes of matter cycling in the soil, which lead to mineralization and repeated synthesis of organic matter whereas nutrients become accessible to plants. In this work, the total number of microorganisms is determined, as the most significant indicator of the soil fertility, in two types of soil: "cernozem" (at the locality Zemun Polje) and "gajnjaca" (at the locality Rača Kragujevačka) in Serbia. The total number of microorganisms is determined depending on the soil type, the manner of its use (ugar and sown maize) and the quantity of the applied N fertilizer. It is examined how the rising quantities of nitrogen fertilizers, N_{30}, N_{60}, N_{120}, N_{160} kg ha^{-1}, affect the total number of microorganisms in relation to the control variation, which was without applied fertilizer. The soil samples for this microbiological analysis are taken on the depth of 0-30 cm. The number is determined by the standard indirect method of sowing of diluted soil samples on the nutritious substratum tripton-soya agar TSA (10^{-5}) and it is expressed in grammes of completely dry soil. The results of the research are analysed by the descriptive statisics method. The total number of microorganisms is different in different types of soil and it shows the dependance on examined factors.

Key words: *microorganisms, different types of soil, nitrogen, maize.*

Introduction

Maize have an important place in crop rotation (Popović, 2010; Živanović et al., 2017; Erić et al., 2018). Microorganisms make a living part of soil (Govedarica et al., 1997) and together with other organisms in soil, they are a component of the most dynamic ecosystems in nature. Different ecophysiological groups of microorganisms live in soil and each of them has a very important and irreplaceable role in the processes that are led within it.

Therefore, heterotrophs as a source of carbon and energy use complete organic compounds, enabling their mineralization in soil (Đukić and Jemcev, 2000). Aminoheterotrophs are a very numerous group of soil microorganisms. On the basis of the research results, Šarčević-Todosijević and Živanović (2017), say that the number of aminoheterotrophs in "cernozem" Zemun Polje varies from $17.4 – 671.5x10^5 g^{-1}$.

In nitrogen cycling, it is especially notable to emphasize the role of *Azotobacter* sp., an organism from the group of free azotofixators, which adopt elementary nitrogen and reduce it to ammonia form and then turn it into organic one (Madigan et al., 1997; Đukić and Jemcev, 2000). Actinomycetes and germs are numerous in soil microflora and have a significant part in a transformation of soil organic matter. Šarčević-Todosijević et al. (2018) say that the

number of actinomycetes in "cernozem" of Zemun Polje is from 0.1 – 17.7x$10^4 g^{-1}$, and in "gajnjača" at the locality Rača Kragujevačka that number is from 2.1 – 9.0x$10^4 g^{-1}$. The total number of microorganisms depends on the soil type, organic matter and water contents, climate, season and antropogenic influences.

In this work, it is determined the total number of microorganisms considering the soil type and quantity of applied nitrogen fertilizer on "ugar" and under the sown maize.

Material and methods

The research of the influence of the soil type and quantity of nitrogen on the total number of microorganisms is carried out in two areas: Eastern Srem (Maize Research Institute, Zemun Polje) and Central Šumadija (Rača Kragujevačka) in Serbia. Microfield testings are done by method of split plots in four repetitions. The research included the three following factors:

1. Soil type (A)
   A_1 – "cernozem" (Zemun Polje)
   A_2 – "gajnjaca" (Rača Kragujevačka)

2. Quantity of nitrogen (B)
   B_1 – Control (without fertilizer)
   B_2 – $P_{90}\,K_{60}\,N_{30}$ kg ha^{-1} (basis, phon)
   B_3 – $P_{90}\,K_{60}\,N_{60}$ kg ha^{-1}
   B_4 – $P_{90}\,K_{60}\,N_{120}$ kg ha^{-1}
   B_5 – $P_{90}\,K_{60}\,N_{180}$ kg ha^{-1}

3. The manner of using soil (C)
   C_1 – "ugar", C_2 – under crop.

The applied agrotechnique during the observations was standard, as the same as for regular maize production.

The soil samples for microbiological analyses were taken on the depth of 0 to 30 centimeters two times, in the phase of a cob blooming and in the phase of physiologic reapness of maize grains. The number of microorganisms was determined by a standard indirect method of sowing diluted soil samples on a nutritious substratum, which was after wards incubated on the temperature of 28^0C (Knežević-Vukčević and Simić, 1999; Đukić and Mandić, 2003). The total number of microorganisms on the nutritious substratum TSA was determined. The number is expressed in grammes of completely dry soil ($10^5 g^{-1}$). The results of the research are analyzed by descriptive statistics method.

Results and discussion

The total number of microorganisms presents a general soil biogenecy (Đukić and Jemcev, 2000) and, as an indicator of fertility, it is in significant and very significant correlative bonds with a number of different ecophysiological groups of microorganisms in soil, as well as with other soil fertility indicators, microbiological biomass of carbon and nitrogen, enzyme activity of soil (Đorđević, 1998; Hajnal-Jafari, 2010; Šarčević, 2010). By the variable analysis, it is confirmed that the total number of microorganisms is significantly affected by all the examined factors and their interactions, Table 1 and 2.

In a phenophase of a maize cob reaping (Table 1), the total number of microorganisms was expressed in "gajnjaca" (108.9 x $10^5 g^{-1}$), in comparison to "cernozem" (100.0 x $10^5 g^{-1}$), but without a statistically significant difference.

The results show that the manner how the soil was used ("ugar" or crop) had a significant impact on the total number of microorganisms. In a phenophase of maize cob blooming, a higher number of microorganisms was determined on "ugar" (121.1 x $10^5 g^{-1}$) than under the sown maize (92.4 x $10^5 g^{-1}$), and the difference was statistically very significant (Table 1).

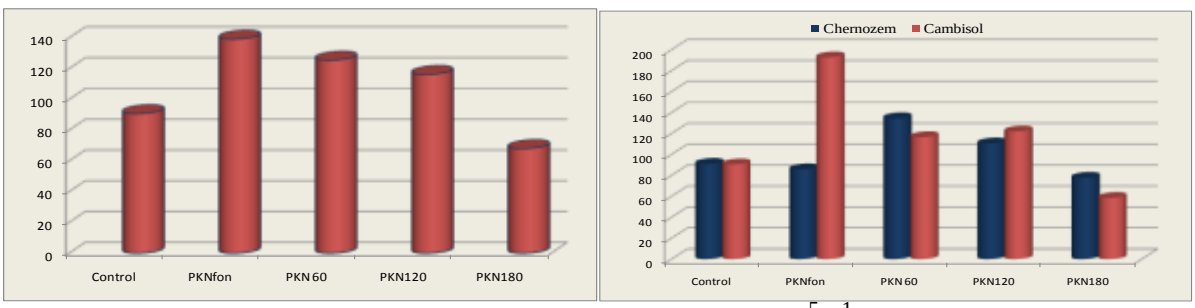
The variable analysis confirmed significant differences in the total number of microorganisms between different applied quantities of nitrogen. In a phenophase of maize cob blooming (Table 1; Graph. 1a and b), the highest number of microorganisms in comparison with control, in average, was in a variation of applying PKN_{phon} (139.3 x $10^5 g^{-1}$), and the least one was in a variation of applying 180 kg ha^{-1} of nitrogen (68.1 x $10^5 g^{-1}$). The differences in the number of microorganisms were highly statistically significant. Lower quantities of applied mineral fertilizers had a stimulative effect on the number of microorganisms and soil biogenecy, where as high concentrations showed an inhibitory effect of nitrogen fertilizers on the number of microorganisms.



Graph 1. a) The total number of microorganisms in soil ($10^5 g^{-1}$) in comparison with the nitrogen quantity, b) The influence of soil type and nitrogen quantity on the total number of microorganisms ($10^5 g^{-1}$) in a phase of maize cob blooming

The highest number of microorganisms, under "ugar", was in a variation of applying PKN_{phon} (139.3 x $10^5 g^{-1}$), whereas the highest number under crops was in a variation of applying 60 kg ha^{-1} of nitrogen (125.6 x $10^5 g^{-1}$). The differences in the number of microorganisms were not statistically significant. In compliance with our research, were the researches of many authors. Milošević (1990) points out that lower concentrations of applied mineral fertilizers have a stimulative effect on the number of microorganisms and soil biogenecy, while high concentrations show an inhibitory effect. Šarčević-Todosijević et al. (2018) mention the noticed effect of stimulation of lower quantities of nitrogen fertilizers on the number of actinomycetes, which confirms similar observation of Epanchinov (1975). Đorđević (1998) mentions that mineral fertilizers, applied in higher or lower quantities on "cernozem" Zemun Polje, very notably affected the total number of microorganisms in a way that lower quantities increased, and higher quantities decreased their number in comparison with control.

Table 2. The influence of soil type, nitrogen concentration and a manner of using soil on the entire number of microorganisms in a phase of physiological reapness of maize grain

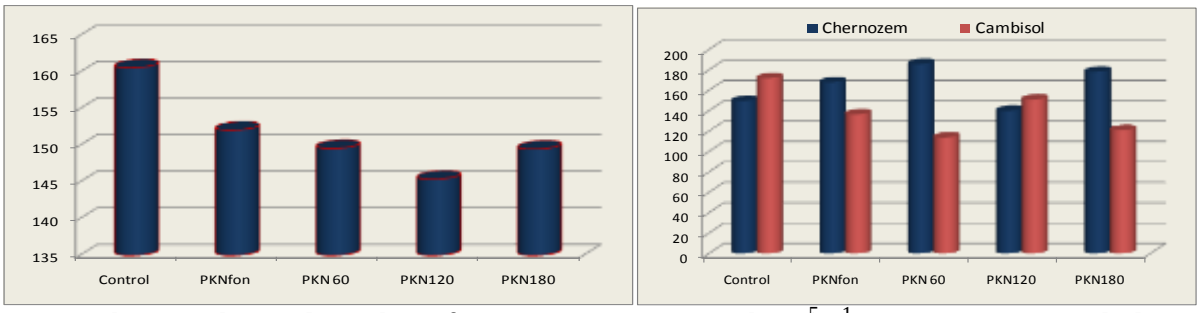
Microorganisms take part in a competition with plants for biogenic elements including them also in biosynthesis of a plasm of their cells (Kuzyakov et al., 2000), so the total number of microorganisms under "ugar" can be the consequence of the absence of such relations. Also,

the role of ugar in soil fertility renewal, accumulating of humus and nitrogen and repression of harmful phenomena which are the result of many years' antropogenic influences and causes of soil strain, was noticed a long time ago (Vukadinović, 1998; Popović, 2010). On the basis of the research results, Šarčević-Todosijević et al. (2016; 2017) and Šarčević-Todosijević and Živanović (2017) say that the number of different ecophysiological groups of soil microorganisms was more expressive on "ugar" than under the sown maize. The difference in the number of microorganisms, in a phase of physiological reapness of maize grain, between "cernozem" and "gajnjaca" statistically was very significant. The total number of microorganisms was more expressive in "cernozem" (164.1 x 10^5g^{-1}) in comparison with "gajnjaca" (138.7 x 10^5g^{-1}), Table 2. In a phase of physiological reapness of maize grain, the total number of microorganisms between treatments under "ugar" and sown maize, was higher under "ugar" (156.0 x 10^5g^{-1}), but the difference was not statistically significant, Table 2, Graph 2a. All the applied quantities of nitrogen induced decreasing of the total number of microorganisms in a phase of physiological reapness of maize grain, in comparison with control (105.6 x 10^5g^{-1}), Table 2, Graph 2b.



Graph 2. a) The total number of microorganisms in soil (10^5g^{-1}) in comparison with the nitrogen quantity, b) The influence of soil type and nitrogen quantity on the total number of microorganisms (10^5g^{-1}) in a phase of physiological reapness of maize grain

The highest number of microorganisms under "ugar" was in a control variation (187.5 x 10^5g^{-1}), whereas the highest number, under crops, was in a variation of applied 180 kg ha^{-1} of nitrogen (160.1 x 10^5g^{-1}). The differences in the number of microorganisms between variations of fertilizers and soil type were statistically significant, Table 2, graph 2. Many researches point to the highest biogenecy in "cernozem", which is conditioned by chemical features of this soil type, humus abundance and mineral clay, lime and absorbed calcium, because of which pH reaction of soil is neutral.

Picture 1. *Bacillus* sp. isolated from the samples of soil type "cernozem" in Zemun Polje

Then follow "gajnjaca", "ritska crnica", where as the lowest values of biogenecy indicators were confirmed in "pseudogley" and "smonica" (Milošević and Govedarica, 1997).

Šarčević-Todosijević et al. (2017; 2018) mention statistically remarkably higher number of *Azotobacter* sp. and actinomycetes in "cernozem" in comparison with "gajnjaca".

Conclusion

The total number of microorganisms in "cernozem" varied from 72.3–204.1 x $10^5 g^{-1}$ and in "gajnjaca" these values were from 54.9 – 184.5 x$10^5 g^{-1}$. By the variable analysis, it is confirmed that the total number of microorganisms was significantly influenced by all the examined factors and their interactions.

A significantly higher total number of microorganisms was confirmed in "cernozem" in comparison with "gajnjaca", in a phase of physiological reapness of maize grain.

The applied quantities of nitrogen had a significant impact on the total number of microorganisms in comparison to control.

The higher total number of microorganisms under "ugar" was confirmed in comparison with maize crops.

Although in soil live different ecophysiological groups of microorganisms, and in different number, they are all united by their feature of enabling developing biogeochemical series of matter cycling which are the base of keeping life on the planet.

Abstract

Marker assisted selection (MAS) is widely implemented into modern grain breeding programs. Molecular markers are used in foreground selection to control the target gene, as well as in background selection to accelerate the reconstruction of the recurrent parent genotype. The best results have been achieved with the qualitative traits, regulated by the action of a single or several genes and clearly phenotypically defined. One successful example of MAS is the improvement of β-carotene content using *crtRB1* specific molecular marker. Maize Research Institute "Zemun Polje" has a breeding program aimed at conversion of standard maize to β-carotene rich genotypes adapted to temperate regions. The objectives of this study were to test the utility of gene-specific SSR marker in foreground selection and to identify polymorphic markers between parental lines to be used in background selection. Genetic variability between two standard and three high β-carotene parental inbred lines was analyzed with 40 SSRs distributed over the maize genom. Total number of alleles detected with 30 informative markers was 77, average being 2.57. The genetic similarity values calculated on Dice coefficient ranged from 0.49 to 0.66. Parental polymorphism for *crtRB1* showed a 543 bp fragment in donor lines, whereas a distinct 296 bp amplicon and a faint 1221 bp amplicon were generated in the recurrent parents. This marker will be used as foreground selection marker for the *crtRB1* gene in the conversion of standard maize to β-carotene enriched lines for growing in temperate regions.

Keywords: *β-carotene, crtRB1 gene, maize, marker assisted selection, SSR.*

Introduction

Maize is an important source of food and nutritional security for millions of people in the developing world, especially in sub-Saharan Africa, Latin America and in many countries in Asia (Shiferaw et al., 2011). However, most of the maize varieties do not contain enough provitamin A (ProVA), the precursor that leads to the formation of vitamin A. Consequently, diets mainly relying on maize may lead to vitamin A deficiency (VAD), primarily in nutritionally demanding periods of life, such as early childhood and pregnancy (Song et al., 2017). The World Health Organization has classified VAD as a public health problem, the leading cause of preventable childhood blindness, anaemia, and weakened host resistance to infection, which can increase the severity of infectious diseases and risk of death (WHO, 2009). Improvement of nutritional quality in food crops (biofortification) is a promising strategy to fight undernutrition, particularly among the rural poor in developing countries (Shiferaw et al., 2011). One of the most important breeding objective is improving the ProVA content of maize grain. Research under the HarvestPlus, Consultative Group on International Agricultural Research Challenge program designed to use breeding for crop biofortification, has provided significant leads for developing ProVA enriched maize (Harjes et al., 2008; Yan et al., 2010). Two genes have the most significant effect on ProVA concentrations in maize grain. One gene, *lcyE* on chromosome 8, encoding lycopene epsilon cyclase is associated with variation in the ratio of various carotenoids in the α- to β-branches of the carotenoid biosynthesis pathway (Harjes et al., 2008). Another gene, *crtRB1* on chromosome 10, encodes

β-carotene hydroxylase enzyme and it has a significant impact on variation for β-carotene concentration in the endosperm (Fu et al. 2013). Babu et al. (2013) reported that *crtRB1* gene had a much larger effect on ProVA concentration than *lcyE*.

CrtRB1 converts β-carotene into β-cryptoxanthin, whose ProVA activity is theoretically only half that of β-carotene. Natural genetic variation in *crtRB1* gene has been reported by Yan et al. (2010). That one favourable allele (*crtRB1* 3′TE) alone is responsible for effecting 2- to 10-fold increase of β-carotene concentration in maize kernel (Babu et al., 2013). The 3′TE (transposable element) polymorphism of the gene that spans the 6th exon and the 3′-UTR (untranslated region) generates three alleles associated with altering β-carotene accumulation: *allele 1* (543 bp; without TE insertion), *allele 2* (296 bp+875 bp; with 325 bp TE insertion) and *allele 3* (296 bp+1221 bp+1880 bp; with 1250 bp TE insertion). *Allele 1* of the *crtRB1* gene is favourable and increases the level of β-carotene, whereas *allele 2* and *allele 3* cause unfavourable effects (Yan et al. 2010).

Muthusamy et al. (2014) reported accelerated development of β-carotene enriched maize, using marker assisted selection (MAS) that holds immense promise as it selects desirable plants precisely and eliminates large scale biochemical estimation in the segregating generations. The introgressed inbreds possessing favourable allele of *crtRB1* can be used in the biofortification program. Moreover, improved hybrids with immense increase of b-carotene (>15 µg/g) can be directly utilised in alleviating VAD worldwide.

Maize Research Institute "Zemun Polje" (MRI) has a breeding program aimed at conversion of standard maize to β-carotene rich genotypes adapted to temperate regions. The main objective of the research presented herein was polymorphism analysis of parental lines used in MAS for β-carotene rich maize. The utility of the SSR marker specific to the *crtRB1* gene in foreground selection was tested. Also, genetic variability between parental lines was analyzed and a set of polymorphic SSR markers was selected to be used in background selection.

Material and Methods

Plant material

Three maize inbred lines provided by the International Maize and Wheat Improvement Center (CIMMYT) were used as the donor parents (DP_1, DP_2 and DP_3) of the favorable allele *crtRB1*-3′TE of the *crtRB1* gene. Two MRI commercial inbred lines were used as the recurrent parents (RP_1 and RP_2). These lines are adapted to the local environmental conditions in Serbia and due to their excellent combining abilities they are components of the leading MRI hybrids.

DNA extraction

Genomic DNA was isolated according to Doyle and Doyle (1987) from the four-weeks-old plants. Bulks were prepared by pooling an equal amount of leaf tissue taken from 20 leaves per line. The DNA was quantified using biospectrometer (BioSpetrometer kinetic, Eppendorf) and diluted to a working concentration of 20 ng/µl. The samples were stored at -20^{0}C until their application in polymerase chain reaction (PCR).

Polymorphism analysis for *crtRB1*

The set of primers used in polymerase chain reaction for the marker specific to the *crtRB1* is presented in Table 1.

Table 1. The set of primers used as a foreground selection marker for the *crtRB1* gene

Primer	Sequence
crtRB1-3′TE-F	5′-ACACCACATGGACAAGTTCG-3′
crtRB1-3′TE-R1	5′-ACACTCTGGCCCATGAACAC-3′
crtRB1-3′TE-R2	5′-ACAGCAATACAGGGGACCAG-3′

Polymerase chain reaction was carried out in 20 µl reaction volume containing: 1×enzyme buffer, 200 µM dNTP, 0.5 µM primers, 1U *Taq* polymerase and 20 ng DNA template. Amplifications were performed in thermocycler Biometra TProfessional Standard 96 with the following program: an initial denaturation at 95ºC/5min, followed by 19 cycles each of denaturation at 95ºC/1min, annealing at 60ºC/1min (-0.5ºC/cycle) and extension at 72ºC/1min; another 19 cycles of 95ºC/1min, 55ºC/1min and 72ºC/1min with final elongation at 72°C for 10 min. The amplified fragments were resolved by 8% polyacrylamide gel electrophoresis (Mini Protean Tetra-Cell, BioRad) at 80 V for 1.5 h. After staining with 0.5 µg/µl ethidium bromide, they were visualized under UV transilluminator and documented in gel documentation system (BioDocAnalyze, Biometra). The size of the amplification products was determined comparing with the 100 bp molecular weight ladder.

Genetic similarity analysis

Simple sequence repeat (SSR) analysis was done with 40 primer pairs spanning over the whole genome. PCR was carried out in 25 µl reaction volume containing: 1×enzyme buffer, 200 µM dNTP, 0.5 µM primers, 1U *Taq* polymerase and 20 ng DNA template. The following touch-down program (thermocycler Biometra TProfessional Standard 96) was performed: an initial denaturation at 95ºC/5min, followed by 15 cycles each of denaturation at 95ºC/30 s, annealing at 63.5ºC/1min (-0.5ºC/cycle) and extension at 72ºC/1min; another 22 cycles of 95ºC/30 s, 56ºC/1min and 72ºC/1min with final elongation at 72°C for four min. The PCR products were separated by electrophoresis on 8% polyacrylamide gel in 1 x TBE buffer, with 100 bp molecular weight ladder as a marker. Gels were run on small format (7.3 x 10 cm) vertical gel system (Mini Protean Tetra-Cell, BioRad), at 80 V for 1.5 h. After staining with 0.5 µg/µl ethidium bromide they were photographed under UV light using Biometra BioDocAnalyze gel documentation system. SSR profiles were converted into a binary matrix based on the presence (1) or the absence (0) of a specific allele. Genetic similarity (GS) was calculated in accordance with Dice (1945): $GS_{ij} = 2a/2a+b+c$; where:

a - the number of fragments present in both variety *i* and *j* (1.1),

b - the number of fragments present in *i* and absent in *j* (1.0),

c - the number of fragments absent in *i* and present in *j* (0.1).

Marker data analyses were performed using statistical NTSYSpc2 program package (Rohlf, 2000).

Results and Discussion

The results presented here are a part of the MRI project on conversion of standard maize to β-carotene enriched lines for growing in temperate regions trough marker assisted backcross breeding. Being the carriers of the favorable allele *crtRB1*-3′TE, three maize inbred lines provided by CIMMYT were used as the donor parents (DP_1, DP_2 and DP_3). As the recurrent

parents, to be the recipients of favourable allele and to improve the β-carotene content, two comercial lines were selected (RP_1 and RP_2).

The first goal of this study was to test the utility of SSR marker specific to the *crtRB1*gene in foreground selection. In any particular cross, it is necessary to run the markers first on the two parents, to confirm the polymorphisms (size differences) for the marker alleles. Similar to Muthusamy et al. (2014), distinct marker polymorphism was observed between the donor and recurrent parents for *crtRB1* gene. The donor parents carried the favorable allele with a 543 bp band (*allele 1*), while the recurrent parents exhibited the unfavorable allele with a 296 bp+1221 bp band (*allele 3*). An illustration of the amplification with this gene specific SSR marker is given in Figure 1.

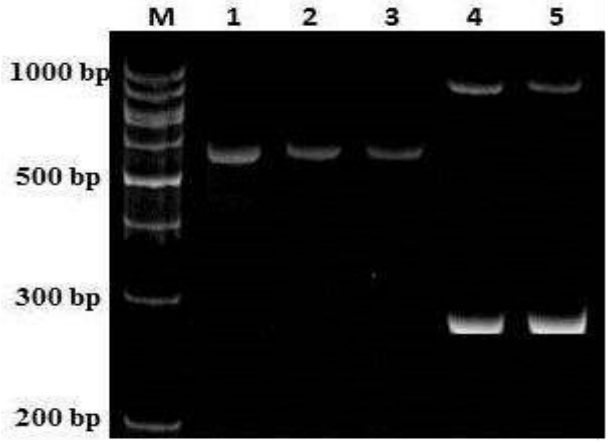

Figure 1. Parental polimorphism with the *crtRB1*-specific SSR marker. M: 100 bp DNA ladder, 1-3: donor parents DP_1, DP_2 and DP_3, 4-5: recurrent parents RP_1 and RP_2.

Being the codominant marker, *crtRB1*-3′TE can detect homozygous dominant, heterozygous and homozygous recessive plants separately. Therefore, it will be used in marker assisted selection for the *crtRB1* gene. Heterozygous plants (*allele 1*/*allele 3*) will be selected in the BC_1 and BC_2 generations, while homozygotes (*allele 1*/*allele 1*) will be selected in the BC_2F_2 generation. Plants without favourable allele will be discarded prior to pollination, hence the size of the breeding population will be reduced. As stated in Choudhary et al. (2016), assessment of genetic relationships among the inbreds is key to success of hybrid breeding programme. Genetic diversity analyses based on molecular markers proved to be very effective in this assessment. This can be extremely helpful for identifying the most appropriate parental lines to be crossed (Ribaut and Hoisington, 1998). Consequently, another goal of this paper was to estimate genetic similarity between parental lines selected for MAS for β-carotene rich maize. Donor and recurrent parent lines were analyzed using 40 SSRs distributed throughout the maize genome. Total number of alleles detected with 30 informative markers was 77, average being 2.57, which is similar to those previously reported in maize inbreds (Maphosa et al., 2011; Bante and Prasanna, 2003; Choudhary et al., 2016). These polymorphic SSR markers will be employed for identification of the genotypes with the highest proportion of recurrent parent genome in BC_2 generation. The pairwise genetic similarity values calculated on Dice coefficient ranged from 0.49 (D_2/RP_2) to 0.66 (D_2/RP_1) (Table 2). These results enable identification of potential high β-carotene hybrid combinations for the biofortification programme. As concluded in Choudhary (2016), genetically diverse and contrasting inbred lines can be used in developing segregating mapping populations for identifying modifier genetic loci influencing β-carotene accumulation.

Table 2. The pairwise genetic similarity values calculated on Dice coefficient between donor (DP_1, DP_2 and DP_3) and recurrent parent lines (RP_1 and RP_2).

	D_1	**D_2**	**D_3**
RP_1	0,62	0,66	0,65
RP_2	0,57	0,49	0,65

Conclusions

The *crtRB1*-3′TE marker showed codominant polymorphism between the donor and recurrent parents. Therefore, it will be used in foreground selection for the *crtRB1* gene. Selected polymorphic SSR markers will be employed in background selection to recover the recurrent parent genome. The results of this analysis constitute the framework for marker assisted introgression of the favourable allele of *crtRB1* into the local maize genotype.

Abstract

This deciduous large shrub, with long arching branches and very abundant white flowers followed by scarlet-red fruit, is suitable for landscape use as an ornamental plant. It is considered as a drought tolerant species that can grow on clay soils. The aim of this study was establishing quick and effective method for vegetative propagation of selected elite genotypes of *Cotoneaster multiflorus* growing in the Belgrade area (Serbia). Two types of softwood cuttings were used: cuttings with current season wood and cuttings with two year old wood. The cuttings were divided into two groups, with cuttings treated with 1% IBA (indole-3-butyric acid) and with cuttings without auxine treatment. After 7 weeks of sticking, rooting percentage as well as number and length of primary roots, and presence and number of secondary roots were determined. Obtained results showed that there were no statistically significant difference in rooting rate among current season wood cuttings (49.3%) and two year old wood cuttings (36.7%), although current season wood cuttings had a better rooting percentage and higher number and length of primary roots. Results obtained in a control treatment without IBA were poor, indicating that auxine treatment was necessary in propagation of this species, and that obtained results could be improved investigating the use of different auxine treatments.

Keywords: *Many-flowered cotoneaster, vegetative propagation, cuttings, greenwood, auxine.*

Introduction

Cotoneaster multiflorus is deciduous large shrub, native to Kazakhstan and Northwest China. It grows up to 4 m tall, with a greater spread up to 4.5 m wide. Its arching, cascading branches are 3-5 m long, developing a mounding habit. The dark-green, simple leaves are alternate, with short petioles, entire margins, up to 5 cm long, turning an attractive yellow in autumn. It flowers from May to June, forming 3-12 flowers per cluster (corymb), that are white and showy, five-petaled, 1 cm wide. In summer, Many-flowered Cotoneaster produces fleshy, ornamental, bright red, globose fruits, about 1 cm in diameter, containing 1-2 seeds (Phipps *et al.*, 1990; Fryer and Bertil, 2009; Dickoré and Kasperek, 2010).

This plant prefers a sunny to half-shady location and fertile, moderately moist, well-drained soil. It can grow on a wide range of soils, from sandy to loamy clay soils, and once established it tolerates drought very well. *C. multiflorus* forms shallow roots and it is suitable for rooftop gardens, medium-high cut hedges and for free-growing high hedges. This plant also provides shelter for birds (Dirr, 1983; Fryer and Bertil, 2009). For these reasons, this ornamental and low-maintenance species should be planted more often in urban green areas, but it is important to select and propagate appropriate genotypes that have been adapted to microclimatic conditions in Belgrade area.

Cotoneaster spp. can be propagated by seed, cutings or grafting (Hartmann *et al.* 2002). Seeds should be soaked for 90 minutes in concentrated sulfuric acid, rinsed, and then stratified for 3 to 4 months at about 4°C. Cuttings should be taken in spring or summer and rooted under mist. Khatamian and van der Hoeven (1997) investigated the influence of IBA concentrations on rooting of *C. multiflorus* softwood cuttings, using quick dip method. Besides their report,

there is no available data for vegetative propagation of *C. multiflorus*. For this reason we decided to conduct research in order to establish rapid and effective method for vegetative propagation of selected elite genotypes of *C. multiflorus* growing in the Belgrade area, in Serbia.

Material and Methods

The elite, vigorous and healthy *C. multiflorus* shrub growing in the urban green area in Belgrade was selected. At the end of May, long, well developed branches were cut and brought in a greenhouse of the Faculty of Forestry in Belgrade. From these branches, 2 groups of green cuttings were taken: nodal with current season's wood only, and nodal from 2-year-old shoots. Cuttings belonging to both groups were 10-15 cm long, each cutting with 4-6 nodes. Before sticking in a sand as a rooting substrate, the cuttings were treated by 0,15% dilution of fungicide Previcur, and their base was dipped in dust preparation of 1% (indole-3-butyric acid) IBA. In the control the auxine treatment was omitted. The rooting was performed under intermittent mist (10 seconds mist with 15 minutes interval).

A total of 600 cuttings (three replications of 50 cuttings per treatment) were used. A randomized experimental design was applied. After 7 weeks, a state of cuttings was determined and the following parameters were measured: a number and length of primary roots, and a number of secondary roots. The significance of differences between the means was determined by the analysis of variance (ANOVA, $p < 0.05$) and the least significant difference (LSD) test. Before the statistical analysis, arcsine transformation was used to convert the percentage data.

Results and Discussion

After 7 weeks, the rooting percentage of cuttings treated with IBA was 36.7% and 49.3% and rooting of non-treated cuttings in a control treatment was significantly lower (Table 1). The cuttings with current season wood rooted poorly in a control treatment, but relatively high percentage of them (21.3%) compared to 2-year-old cuttings (1.3%) was recorded with root primordias, thus indicating that cuttings taken from young shoots have a higher rooting potential, which can be confirmed by the results of numerous anatomical studies of woody species (Lovell and White, 1986).

The high number of cuttings developed a callus that may delay or inhibit the formation of adventitious roots (Hartmann *et a*l. 2002). Wounding of basal callus tissues and applications of rooting hormones can result in rooting of callused cuttings (Silva *et al*., 2002), but effectiveness of this treatment should be additionally investigated.

Table 1. State of cuttings seven weeks after sticking

Cutting type	Hormone	State of cuttings				
		rooted (%)	with root primordias (%)	unchanged (%)	callusing (%)	necrotic (%)
1-year-old	1% IBA	49.3^{a}	3.3^{b}	2.0^{b}	16.6^{b}	28.6^{a}
1-year-old	control	14.7^{bc}	21.3^{a}	14.6^{ab}	45.3^{a}	4.0^{b}
2-year-old	1% IBA	36.7^{ab}	1.3^{b}	0.6^{b}	36.0$^{a\ b}$	25.3^{a}
2-year-old	control	8.6^{c}	0.0^{b}	24.0^{a}	42.0^{a}	25.3^{a}

Values followed by different letters are significantly different at the $P < 0.05$ level according to the LSD test

The root system of cuttings treated with IBA was well developed, both for cuttings with current season wood and cuttings taken from 2-year-old shoots (Table 2). There was no significant difference between these two types of cuttings regarding mean number of primary and secondary roots, but the younger cuttings developed longer roots.

Table 2. Number and length of roots

Cutting type	Hormone	Mean No. of primary roots	Mean length of primary roots (cm)	Mean No. of secondary roots
1-year-old	1% IBA	4.8 [a]	11.3[a]	10.5 [a]
1-year-old	control	1.4 [b]	0.3[c]	1.3 [b]
2-year-old	1% IBA	4.1 [a]	5.7[b]	6.3 [a]
2-year-old	control	2.3 [b]	0.7[c]	1.3 [b]

Values followed by different letters are significantly different at the $P < 0.05$ level according to the LSD test

These results indicate that auxine treatment is necessary for rooting, and a similar finding was reported by Khatamian and van der Hoeven (1997). However, they applied IBA using quick dip method, and the best result (100 % rooted cuttings) was recorded using 5000 ppm IBA for 10 seconds, which is high concentration. Kroin (1992) stated that recommended concentration for rooting softwood cuttings using the quick dip method for the majority of wooden species is 1000 ppm IBA, and for hardwood cuttings is 2000 ppm IBA. For difficult to root hardwood cuttings Kroin (1992) suggests using 5000 ppm IBA up to 20000 ppm IBA.

In addition, Khatamian and van der Hoeven (1997) performed rooting in a mixture of 30% Canadian sphagnum peat and 70% perlite, and the substrat composition can also affected the success of rooting, including rooting rate, development of roots and/or callus (King *et al*., 2011; Witcher and Pounders, 2016).

Results obtained with other *Cotoneaster* species, also suggest importance of IBA use. Thus Kalyoncu *et al.* (2017) researching the rooting of *C. horizontalis* apical softwood cuttings obtained high rooting rate (100%) in all treatments, including control, but cuttings tretaed with 4000 ppm IBA developed significantly higher root number. However, Hocking and Thomas (1981) reported occurence of basal necrosis of *C. conspicua* cuttings when concentration of IBA was increased from 0.4% to 2%.

Conclusions

Selected elite genotype of *C. multiflorus* suitable for growing in the conditions of Belgrade area can be vegetatively propagated by nodal softwood cuttings, taken from current season shoots, treated with 1% IBA using a dry dip method. However, obtained rooting percentage can be improved using a quick dip method of IBA application, which should be further investigated by additional research. Also, use of different rooting media and apical cuttings should also be considered.

Abstract

Lycium barbarum is a deciduous shrub that has been used for centuries in China as a traditional medicinal and food supplement. Today, it is widely grown as a fruit as well as a landscape ornamental species, including some ornamental varieties. It is easily grown plant, suitable for hedges, and it endures pruning. Goji has well developed root system and it can be planted for erosion control or to stabilize sandy soils. It can be propagated by seed, cuttings, layering and division. Propagation by cuttings is the most convenient method for mass production of uniform plants. In order to establish an efficient production system, the influence of different substrates on rooting of hardwood cuttings was examined. Six substrate mixtures were tested: sand, sand and compost (1: 2), sand and peat (1: 2), pine bark and compost (1: 1), pine bark and peat (1: 1), pine bark and sand (1: 1). Except for rooting percentage, success of rooting was determined using following parameters: the number and length of primary and secondary roots, number and length of shoots. The best results were obtained in sand. The rooting percentage was the highest (66%), and the length of primary roots, number and length of shoots were higher compared to other treatments. The influence of pH value of substrates on rooting performance was also discussed.

Keywords: *Goji, vegetative propagation, cuttings, rooting medium.*

Introduction

Lycium barbarum (wolfberry, goji) is a deciduous shrub growing to 2.5 m, spreading up to 4 m, developing the long arching branches, with the side branches often reduced to a short leafless spines. It flowers from June to August, and the fruit is orange or dark red berry, 2 cm in diameter, ripen from August to October (Flint, 1997; Maughan and Black, 2015). Goji has been used for centuries in China as a traditional medicinal and food supplement, and today it is becoming popular worldwide due to its medicinal proprieties and benefits for consumption (Kulczyński and Gramza-Michałowska, 2016; Gao *et al.*, 2017).

Wolfberry is also easily grown, low-maintenance, landscape ornamental plant. It succeeds in nutritionally poor soil, and can be planted to stabilize sandy banks. Goji is suitable for planting in groups or in informal hedges and it is very tolerant of pruning and can regrow from old wood (Huxley and Griffiths, 1992). Goji is also salt tolerant species (Juan *et al.*, 2004). It can be easily propagated by seed, but vegetative methods are more convenient for clonal production of desired genotypes. Goji can be propagated by division of suckers in late winter and by layering (Huxley and Griffiths, 1992; Maughan and Black, 2015), but these methods are suitable for small scale production. Also, there are some reports regarding micropropagation of this species (Cao *et al.*, 1999; Hu *et al.*, 2008; Fira and Clapa, 2011; Osman *et al.*, 2013*;* Ciorchină *et al.*, 2018), but it is expensive method and it is not widely used. The most convenient method of large scale production of uniform wolfberry plants is by cuttings (Huxley and Griffiths, 1992). The majority of research regarding optimization of vegetative production of Goji by softwood, semi-hardwood and hardwood cuttings was conducted in China (Shen and Chen, 1990; Qiong, 2011; Zheng *et al.*, 2012; Zong-Cai *et al.*, 2012; Wang *et al.*, 2016). These studies examined the effect of different growth regulators on

rooting and development of Goji cuttings taken from local genotypes. Besides commonly used, auxine based growth regulators (such as IBA - Indole-3-butyric acid), they investigates the effect of plant growth regulators invented in China, including ABT rooting powder series (invented by Chinese Academy of Forestry). However, one of the important factors that influence rooting performance of cuttings is a composition of the rooting media (Altman and Freudenberg, 1983; Caspa *et al.*, 2009; Gehlot *et al.*, 2014, 2015; Asanica *et al.*, 2016). For this reason, we decided to test the influence of different substrates (commonly used in Serbian nurseries) on rooting of Goji hardwood cuttings in order to establish an efficient, cost-effective and applicable production system.

Material and Methods

At the end of February, the cuttings were taken from 3-year old container plants with multiple shoots developed, grown outdoors. In this time, the stock plants didn't have leaves, and the temperature during a day didn't drop below 5°C. The average length of nodal hardwood cuttings was 9.5 cm, and diameter was 2.8 mm. The cuttings were randomly placed in the 104-cell plugs containing different substrate mixtures: sand, sand and compost (1: 2), sand and peat (1: 2), pine bark and compost (1: 1), pine bark and peat (1: 1), pine bark and sand (1: 1). The pH value of each media mixture was measured (Table 1) according to Bacto Laboratories methodology (http://www.bacto.com.au/measurement-of-ph-in-soil/).

Table 1 Rooting substrates used in the research

Substrate mixture	pH value
sand	7.0
sand and compost (1: 2)	7.0
sand and peat (1: 2)	5.5
pine bark and compost (1: 1)	6.0
pine bark and peat (1: 1)	5.0
pine bark and sand (1: 1)	5.0

The cell plugs with cuttings were placed in the cold frame greenhouse of the Faculty of Forestry and kept 14 months before examining the results. Irrigation was adjusted according to a daily temperatures, using manual irrigation during cold months (March, April, September, October) and a mist system during summer months. At the begining of April next year, following parameters were determined: sum of primary root lengths, number of primary and secondary roots, sum of shoot lengths, number of shoots and number of cuttings with proliferated buds. Three replications of 33 cuttings per treatment were used, for each treatment 99 cuttings (total 594 cuttings). Obtained results were analysed statistically and the significance of differences between the means was determined by the analysis of variance (ANOVA, $p < 0.05$) and the least significant difference (LSD) test. Before the statistical analysis, arcsine transformation was used to convert the percentage data.

Results and Discussion

The rooting medium strongly influenced rooting percentage (Table 2). The best result was obtained in sand (66.6%), whereas mixture of equal parts of sand and pine bark was the most unfavorable with the only 22.2% rooted cuttings, and with only 0.7% of cuttings with proliferated buds. The longest shoots also developed from cuttings rooted in a sand. Besides composition of rooting medium, the pH value can also influence rooting (Kumar *et al.*, 2011;

Fisher *et al.*, 2016). However, rooting percentage in the mixture of sand and peat (1: 2) with pH 5.5 was similar to rooting in media with pH 7, and significantly higher than medium with pH 5.0 (pine bark and sand). Kumar *et al.* (2011) found that pH influence effectiveness of auxine for induction and growth of adventitious roots of *Gmelina arborea*, and in their research addition of IBA was ineffective at pH 5.5–7.0 and inhibitory at pH 8.5. However, our research was conducted without auxine treatment.

Table 2. Rooting of hardwood Goji cuttings

Substrate mixture	Rooting percentage (%)	Cuttings with proliferated buds (%)	Sum of shoot length per cutting (cm) ± SE
sand	66.6^{a}	32.0^{ab}	$11.5^{a} \pm 1.33$
sand and compost (1: 2)	53.5^{ab}	34.0^{a}	$6.3^{bc} \pm 0.99$
sand and peat (1: 2)	51.5^{ab}	23.0^{bc}	$8.6^{b} \pm 0.31$
pine bark and compost (1: 1)	46.4^{b}	21.0^{c}	$4.0^{cd} \pm 1.01$
pine bark and peat (1: 1)	42.4^{b}	21.0^{c}	$4.6^{cd} \pm 1.29$
pine bark and sand (1: 1)	22.2^{c}	0.7^{d}	$2.6^{d} \pm 1.58$

Values followed by different letters are significantly different at the $P < 0.05$ level according to the LSD test

The highest number of primary roots was formed in mixture of sand and compost (Table 3). However, the cuttings rooted in a sand had the highest number of secondary roots and they also developed significantly longer roots.

Table 3. Number of primary and secondary roots and average sum of primary root length

Substrate mixture	No of primary roots ± SE	No of secondary roots ± SE	Sum of primary root length per cutting (cm) ± SE
sand	$1.4^{b} \pm 0.15$	$3.4^{a} \pm 0.53$	$19.4^{a} \pm 1.06$
sand and compost (1: 2)	$2.7^{a} \pm 0.45$	$1.4^{bc} \pm 0.63$	$6.5^{b} \pm 1.90$
sand and peat (1: 2)	$1.3^{b} \pm 0.16$	$1.7^{b} \pm 0.57$	$5.1^{b} \pm 0.99$
pine bark and compost (1: 1)	$1.2^{b} \pm 0.33$	$1.1^{bc} \pm 0.54$	$4.7^{b} \pm 2.10$
pine bark and peat (1: 1)	$1.4^{b} \pm 0.48$	$0.7^{cd} \pm 0.31$	$7.7^{b} \pm 3.81$
pine bark and sand (1: 1)	$0.5^{c} \pm 0.24$	$0.11^{d} \pm 0.243$	$2.1^{b} \pm 1.69$

Values followed by different letters are significantly different at the $P < 0.05$ level according to the LSD test

The obtained results showed importance of rooting media in a vegetative production of Goji. However, Qiong (2011) stated that the use of plant growth regulators (PGRs) is necessary for successful propagation of this plant. Nevertheless, the application of PGRs should be carefully investigated. For example, Asanica *et al.* (2016) obtained 60% rooted Goji cuttings (0.4 - 0.8 cm diameter) in a control treatment in a peat and sand (1: 1) mixture, 50% rooted cuttings after treatment with 1500 ppm IBA, and only 40% rooted after treatment with 500 ppm IBA. However, their results with thiner cuttings (0.1 - 0.3 cm) were significantly different, reaching 90% rooting of cuttings treated with 500 ppm IBA, rooted in a same substrate mixture. Gehlot *et al.* (2015) showed that success of hardwood cuttings rooting depends of several factors and their interactions, including cuttings diameter, PGRs type and concentration and a rooting medium. Genotype is also important factor, and each clone could

have a different response to a treatments, and the rooting rate can vary from 30% to 100% depending on genotype (Asanica *et al.*, 2016).

The number of roots obtained in our research was relatively low, up to average of 2.7 primary roots per cutting. Wang *et al.* (2016) investigated the effect of ABT-6 rooting agent on the hardwood cuttings of *L. barbarum* var. *implicatum.* They obtained the best results using quick dip method (400 mg/L ABT-6), with high rooting percentage (82.3%) and very high number of shoots (6.6) and roots (8.9), which was long and well developed. For this reason, the use of different PGRs should also be considered for the successful vegetative propagation of Goji.

Conclusions

The rooting media composition significantly influenced the success of rooting of wolfberry hardwood cuttings. The best results, with highest rooting percentage (66%), and the longest shoots and roots was obtained in sand. However, the use of different PGRs and should be considered in order to improve production effectiveness of this valuable ornamental, edible and medicinal species.

Abstract

Central Serbia, besides Vojvodina, is the most important crop production region in Serbia. The climate is the main difference between central Serbia and the Autonomous Province of Vojvodina. The first region is characterised with somewhat lower precipitation sums during the growing season and with temperatures a bit lower during the whole year. Due to this, every year, the Maize Research Institute, Zemun Polje performs production trials with its most distributed commercial hybrids in both regions. In this study, 10 commercial ZP maize hybrids were tested in 85 locations in central Serbia in the period 2014-2017. The number of locations per year amounted to: 26, 22, 23 and 14 in 2014, 2015, 2016, 2017 respectively. The average maize grain yields were recorded in 2014 and 2015, while 2016 was exceptionally high yield year. On the other hand, drought in 2017 reduced the yield. Yield stability was estimated by the method developed by *Eberhart* and *Russel*. The lowest four-year average yield (7.199 t ha^{-1}) was recorded in the hybrid ZP 341. This hybrid was also unstable (b_i=0.729). The highest yield was recorded in the hybrid ZP 600 (9.506 t ha^{-1}). The highest yield stability was estimated in the hybrid ZP 606 (b_i=0.954), which was also high yielding (8.688 t ha^{-1}). The most yielding hybrid ZP 600 was at the same time the least stable (b_i=2.483) and adjustable to favourable growing conditions.

Key words: *maize, grain yield, stability performance.*

Introduction

Maize is one of the most important crops not only in our country but also worldwide. It was domesticated in Central America approximately 7700 years ago. Maize represents a plant species that is evolutionarily most developed in the entire plant kingdom (Glamočlija, 2004). Maize is one of the leading species in the global agricultural production ranking high in the world economy. It ranks first according to total production quantity and grain yield per area unit and second according to harvested areas in the world (FAOSTAT, 2013). The revolution in maize production began with the discovery of heterosis and cultivation of hybrids in the USA during the 1930s (Duvick 2005). Besides selection for high and stable yields, maize growing practices has also changed. It is believed that about 60% increase in grain yield ~~is~~ results from the development of new hybrids, while the remaining 40% is a result of new technological solutions and education of maize producers (Jocković et al. 2010).

Breeding and selection of maize hybrids of high genetic yield potential have been performed at the Maize Research Institute, Zemun Polje for the past 70 years. All maize hybrids developed at the Institute can be classified into six cycles of selection (http://www.mrizp.rs/en/research-l/breeding). Each cycle of selection produced hybrids that have been better adopted to agro-ecological conditions and they have been characterised by a higher genetic potential of the yield.

Central Serbia, besides Vojvodina, is the most important crop production region in Serbia. The climate is the main difference between central Serbia and Vojvodina. The first region is characterised with somewhat lower precipitation sums during the growing season and with temperatures a bit lower during the whole year. Due to this, every year, the Maize Research

Institute, Zemun Polje performs production trials with its most distributed commercial in both regions.

The aim of this study was to observe yields of Zemun Polje (later ZP) commercial maize hybrids and to establish grain yield stability not only in central Serbia but also in its three production regions: Mačva and Podrinje (the Drina river basin), Podunavlje (the Danube river basin) and Braničevo and central and eastern Serbia.

Materials and methods

In this study, 10 commercial ZP maize hybrids of different maturity groups (FAO 300-600) were tested in 85 locations in central Serbia in the period 2014-2017. All grown hybrids are commercial and widespread through the whole of Serbia. Production trials were set up at: 26, 22, 23 and 14 locations in 2014, 2015, 2016, 2017 respectively.

The elementary plot size amounted to 0.1 ha. Sowing and harvest of the trial was done mechanically. The plant density per hectare varied over FAO maturity groups and it ranged from 70,000 (FAO 300-400) to 60,000 plants ha^{-1} (FAO 500-600). Grain yield was calculated in t ha^{-1} at 14% moisture.

The average grain yield was estimated cumulatively for all 85 locations, and separately for Mačva and Podrinje (the Drina river basin), Podunavlje (the Danube river basin) and Braničevo and central and eastern Serbia, as they are two separate agro-ecological environments for maize cultivation. The method after Eberhart and Russell (1966) was applied to determine stability parameters for both all 85 locations cumulatively and Mačva and Podrinje (the Drina river basin), Podunavlje (the Danube river basin) and Braničevo and central and eastern Serbia separately.

Eberhart and Russell method is represented by the following equation:

$Y_{ij} = m + b_i I_j + d_{ij}$

Y_{ij} - the average yield of the i^{th} genotype in the j^{th} location

m - the average yield of the i^{th} genotype at all locations

b_i – standardised regression coefficient of the environment and genotype, genotype relationship to the environment

I_j - index of the environment as the average of all genotypes in the j^{th} location, reduced from the total average

d_{ij}-deviation from regression of the i^{th} genotype in the j^{th} location

The standardised regression coefficient (b_i) shows the response of genotypes to environment. When b_i=1, then the average adaptability and stability of the tested genotypes was considered uniform under the influence of favourable and poor environment conditions; when $b_i > 1$, genotype was considered stable and good only in favourable environment conditions, and when the $b_i < 1$, genotype was considered to perform better than the average in less favourable growing conditions and environments. All calculations were done in the Excel programme.

Results and discussion

The average maize grain yields were recorded in 2014 and 2015, while 2016 was exceptionally high yield year. On the other hand, drought in 2017 reduced the yield.

In central Serbia the lowest four-year average yield (7.199 t ha^{-1}) was recorded in the hybrid ZP 341. This hybrid was also unstable (b_i=0.729). The highest yield was recorded in the hybrid ZP 600 (9.506 t ha^{-1}). The highest yield stability was estimated in the hybrid ZP 606 (b_i=0.954), which was also high yielding (8.688 t ha^{-1}). The most yielding hybrid ZP 600 was at the same time the least stable (b_i=2.483) and adjustable to favourable growing conditions (Table 1).

Table 1. Grain yield and stability parameters of ZP hybrids in 85 locations in central Serbia for the 2014-2017 period.

Hybrid	Grain Yield (t/ha)	Rank according to grain yield	bi	Rank according to b_i
ZP 341	7.199	10	0.729	9
ZP 366	7.589	9	0.739	7
ZP 388	7.684	7	0.801	6
ZP 427	7.782	6	0.809	5
ZP 434	7.609	8	0.748	8
ZP 555	8.150	5	0.909	3
ZP 560	8.323	3	0.919	2
ZP 600	9.506	1	2.483	10
ZP 606	8.688	2	0.954	1
ZP 666	8.231	4	0.908	4
Average	8.076		1	

The highest average grain yields in the region of Mačva and Podrinje were recorded in hybrids ZP 600 (8.725 t ha^{-1}) and ZP 560 (8.636 t ha^{-1}), while the lowest yield was established in the hybrid ZP 341 (7.442 t ha^{-1}), which was, at the same time, the least stable hybrid (b_i=0.892). Values of the regression coefficient show that the hybrid ZP 434 (b_i=0.994) was the most stable in this growing region, while the hybrid ZP 666 (b_i=0.966) ranked second, and also had a very low grain yield (7.840 t ha^{-1}) (Table 2).

Table 2. Grain yield and stability parameters of ZP hybrids in locations in Mačva and Podrinje for the 2014-2017 period.

Hybrid	Grain Yield (t/ha)	Rank according to grain yield	bi	Rank according to b_i
ZP 341	7.442	10	0.892	10
ZP 366	7.964	6	0.921	9

ZP 606	8.494	3	1.060	7
ZP 666	7.840	9	0.966	2
Average	8.099		1	

The highest yields in the regions of Podunavlje and Braničevo were recorded in hybrids ZP 600 (11.290 t ha^{-1}) and ZP 606 (8.744 t ha^{-1}). Furthermore, the hybrid ZP 341 had the lowest yield in this region too (7.038 t ha^{-1}). The highest yield stability was expressed by hybrids ZP 606 and ZP 666 (b_i=0.820 and b_i=0.800, respectively), while the top yielding hybrid ZP 600 was the least stable (b_i=3.964) and adjustable to favourable growing conditions (Table 3).

Table 3. Grain yield and stability parameters of ZP hybrids in locations in Podunavlje and Braničevo for the 2014-2017 period.

Conclusion

The average maize grain yields were recorded in 2014 and 2015, while 2016 was exceptionally high yield year. Drought in 2017 reduced the yield. Thus, agro-ecological conditions in these four years were ideal for testing stability and adaptability of hybrids. ZP maize hybrids showed good results related not only to grain yields but also to yield stability. The hybrid ZP 600 was top yielding (9.506 t ha^{-1}) in all 85 locations, and at the same time expressed the lowest yield stability and good adaptability to more favourable growing conditions. While testing hybrid stability, it is possible that the highest yielding hybrids show a below-average stability (Babic, 2006). The highest yield stability was estimated in the hybrid ZP 606 (b_i=0.954), which also ranked second by its yield (8.688 t ha^{-1}). The most yielding hybrid ZP 600 was at the same time the least stable (b_i=2.483) and well adjusted to favourable growing conditions. Based on the four-year average it can be concluded that hybrids of earlier maturity groups (FAO 300-400) had lower grain yields than medium late and late maturity hybrids, which is not in accordance to results obtained by Pavlov et al. (2011), hence they might be recommended for cultivation under agro-ecological conditions of central Serbia.

Abstract

Fusariosis is one of the most common and most important diseases of maize. Every year, *Fusarium graminearum* (Schwabe) reduces grain yield and quality in both commercial and seed production. This species is probably one of the most destructive pathogens. The damages it causes increase due to mycotoxin synthesis-ability. The determination of a correlation between aggressiveness and synthesis-ability of deoxynivalen and zearalenone in isolates originating from wheat and maize grain was the aim of this study. The pathogenicity of 30 isolates of *F. graminearum* was tested after Reid et al. (1996). Artificial inoculation of ears was done by injecting 2 ml of conidial suspension ($1x10^5$) into silk channels on the second day after maize silked. The estimation of the degree of pathogenicity was based on the determination of symptoms of fusarium maize ear rot on the 1-7 scale. The mycotoxin concentration was determined by the ELISA according to the manufacturer's instructions (Tecna, Italy, CelerDON, ZEA Test Kit). Isolates exhibited pathogenicity on maize ears and synthesised both mycotoxins. The correlation between aggressiveness and DON, i.e. ZEA synthesise-ability was statistically significant, i.e. not statistically significant, respectively.

Keywords: *Fusarium graminearum*, maize, deoxynivalenon, zearalenone.

Introduction

Small grains and maize dominate the overall crop production in Serbia, both per area unit and total yield. However, the cereal production is endangered by a large number of pathogens, particularly of species of the genus *Fusarium*, which are widely distributed in all parts of the world. This genus is the most important genus in agriculture, whose pathogenic species infect plants and synthesise mycotoxins (Stanković et al., 2007). Due to great variability, the species of this genus are adapted to different agroecological conditions of cultivation (Stanković et al., 2007). Although the data on fusarioses exist for more than two centuries, more attention was paid to them only during the last decades of the 20th century (Logrieco et al., 2002). Fusarioses of plants are present to a certain percentage every year, and in years of epidemics they can reduce the yield by 70-90% (Stanković et al., 2012).

Agroecological conditions in Serbia favour, to a greater extent, the development of pathogenic and toxigenic species of the genus *Fusarium*. The most common species of this genus belong to the sections *Discolor* (*Fusarium graminearum* Schwabe and *F. avenaceum* (Fr.) Sacc.) and *Liseola* (*F. verticillioides* Sheldon) (Stanković et al., 2007). During the past two decades, the species *Fusarium graminearum* has been standing out as one of the most destructive causal agents of diseases on cereals, as it can cause yield losses of several billion dollars (Clear and Patrick, 2000; Windels, 2000). *F. graminearum* is one of the most isolated species from infected maize plants in Europe (Logrieco et al., 2002). The importance of *F. graminearum* is not only reflected in yield reductions, but also in the reduction of grain quality due to synthesis-ability of mycotoxins in infected plants and the adverse impact on human an animal health.

Fusariotoxins belong to the group of the most commonly identified mycotoxins in nutrients. *Fusarium* species synthesise a broad spectrum of mycotoxins, but their concentration is not always proportional to the intensity of fusarioses (Champeil et al., 2004; Wegulo**,** 2012; Krnjaja et al., 2015). The origin of over 300 toxic fungal metabolites, of which 139 are fusariotoxins, have been identified (Logrieco et al., 2002; Leslie and Summerell, 2006). The most common among them are trichothecenes (deoxynivalenol-DON), followed by zearalenones (ZEA) and fumonisins (FB1), which differ in the chemical structure, mechanism of action and characteristic symptoms of diseases caused in humans and animals. *F. graminearum* synthesises over 17 types of mycotoxins: ZEA, DON, mono-acetyldeoxynivalenol, nivalenol (NIV), trichothecene type A, culmorin, fusarin C, fuzarohormanon and steroids (Logrieco et al., 2002; Leslie and Summerell, 2006).

The species of the genus *Fusarium*, exhibit a high degree of interspecies and intraspecies variability relating to both toxigenic and pathogenic properties. Isolates may vary from non-pathogenic to very pathogenic to a certain plant species. Moreover, one species can be pathogenic to one and non-pathogenic to another plant species. Many authors have established the existence of variability in the degree of pathogenicity or aggressiveness of the *F. graminearum* isolates in the world (Carter et al., 2002; Brennan et al., 2003; Mesterházy et al., 2005; Krnjaja et al., 2007, 2008). Due to toxigenic properties for humans and animals, certain species of the genus *Fusarium* are given greater importance as more potentially toxigenic than as pathogenic species.

Materials and methods

Thirty isolates of *F. graminearum* originating from the maize and wheat kernels were used in the study. The pathogenicity of isolates was tested after Reid et al. (1996). Artificial inoculation of maize ears was done by injecting 2 ml of conidial suspension ($1x10^5$) into silk channels on the second day after maize silked. The inoculum was prepared of the 14-day culture isolate cultivated on the SNA (synthetic nutrition agar) under the combination of fluorescence and ultra-violet light at 20ºC. The pathogen was directly inserted into the host tissue by a sterile syringe. Five plants in four replicates were inoculated per each isolate. The same procedure was applied to control plants, but instead of the inoculum, sterile distilled water was used. The estimation of the degree of pathogenicity was performed at the stage of maize harvest maturity based on characteristic symptoms of gibberella ear rot of maize on the 1-7 scale (Reid et al., 1996).

The sample preparation for qualitative and quantitative mycotoxicological analyses was done on sterile maize kernels in accordance with the method described by Logrieco et al. (1995). Samples were analysed for the presence of DON and ZEA using ELISA (Enzyme linked immunosorbent assay). The quantitative determination of mycotoxin concentrations was done at the wave number of 450 nm by ELISA reader spectrophotometer (BioTek EL x 800^{TM}).

The Pearson Product-Moment Correlation Coefficent was used to establish the relationship between aggressiveness and mycotoxin concentrations.

Results and discussion

The pathogenicity of all tested *F. graminearum* isolates was confirmed after artificial inoculation of the maize ear. The obtained results indicated that all tested isolates were pathogenic, because they caused the occurrence of characteristic symptoms of gibberella ear rot. Depending on the aggressiveness of the isolates, ears were completely or partially infested by fungal mycelia. Husk was tightly adhered to ears in isolates that expressed stronger pathogenicity. Symptoms of the disease did not occur on ears that were inoculated with sterile distilled water as a negative control. The average assessment of the infection intensity varied in maize and wheat from 2.16 (isolate 1368) to 4.47 (isolate 699) and from 2.11 (isolate 795)

to 4.99 (isolate 1485), respectively. The comparison of average values shows that isolates originating from maize expressed stronger aggressiveness (3.14) than isolates originating from wheat (2.79) (Table 1). Studying the variability of pathogenic properties of *Fusarium* spp. originating from kernels of maize and wheat grown in Serbia, Tančić et al. (2009) observed that intraspecies variability in aggressiveness was most pronounced in *F. graminearum* isolates. Moreover, these authors stated that *F. graminearum* isolates derived form wheat kernels had expressed less pathogenicity than isolates derived from maize kernels. The pathogenicity of *F. graminearum* isolates has been studied in many countries throughout America and Europe (Brennan et al. 2003; Fernandez and Chen 2005; Broders et al., 2007; Kuhnem et al., 2015). Fernandez and Chen (2005) have analysed the pathogenicity of *Fusarium* species in Canada and established that species *F. graminearum* and *F. culmorum* were the most pathogenic on wheat, while species *F. equiseti* and *F. poae* were least pathogenic. Aggressiveness under *in vitro* conditions of 112 of *F. graminearum* isolates originating from 30 locations in 13 countries showed that all observed isolates were very pathogenic on maize seeds and moderately to highly pathogenic on soya bean seeds (Broders et al., 2007). The aim of studies carried out by Kuhnem et al. (2015) was to determine whether *F. graminearum* isolates originating from wheat and maize had been more aggressive on host plants and whether the aggressiveness further affected the production of trichothecenes. These results indicated that the aggressiveness of isolates had widely varied in both wheat and maize, and that there had not been statistically significant differences in aggressiveness among isolates of different origins.

Table 1. Pathogenicity and production ability of *F. graminearum* isolates

Maize-derived isolates	Rate	Mycotoxin		Wheat-derived isolates	Rate	Mycotoxin	
		DON (µg/g)	ZEA (µg/kg)			DON (µg/g)	ZEA (µg/kg)
699	4.47	334.4	68.93	203	2.56	40.2	12.93

2624	2.42	84.5	46.53	2820	2.9	44.2	29.52
2812	2.95	72.6	1.12	1485	4.99	184.6	117.98
average	**3.14**	**85.09**	**37.38**	**average**	**2.79**	**70.36**	**45.21**

The ELISA was used to determine the synthesis-ability of ZEA and DON of the observed *F. graminearum* isolates, as the most important toxigenic property. All studied isolates expressed synthesis-ability of mycotoxins DON and ZEA. The ZEA concentration varied among isolates originating from both the same host and different hosts. The range of variation in concentrations in maize-derived isolates was greater (1.12-123.17 µg/kg) than in wheat-derived isolates (4.26-117.98 µg/kg) (Table 1). The analyses of synthesis-ability of mycotoxins of species of the genus *Fusarium* in the world have produced very divergent

results. It is considered that the reason for this is the different origin of isolates and climatic conditions of the given environment, as well as, nonconforming methods and standards applied in the mycotoxin analyses (Lević, 2008). Wheat-derived isolates produced greater average concentrations of ZEA (45.21 μg/kg) than maize-derived isolates (37.38 μg/kg). However, Tančić et al. (2015), studying the variability in the ZEA production in different species of the genus *Fusarium*, observed that there were no significant differences between average concentration and the range of concentrations in *F. graminearum* isolates derived from wheat and maize in Serbia. The average concentrations of ZEA synthesised by isolates observed in this study were far lower that the average ZEA synthesis in *F. graminearum* isolates (30.600 μg/kg) analysed by Tančić et al. (2009). Studies of the variability of species of the genus *Fusarium* and fusariotoxins in Serbia indicate that *F. graminearum* had the greatest variability in synthesis-ability of ZEA. Obtained results on ZEA synthesis are in accordance with the results on synthesis-ability of *F. graminearum* isolates gained by Jajić et al. (2007) (from the detection threshold to 220 μg/kg). Kuhnem et al. (2015) studied synthesis-ability of ZEA of the *F. graminearum* isolates derived from wheat and maize and established a great range of variation in concentrations of this mycotoxin (100 to 97.520 μg/kg). By studying toxigenic potential of *F. graminearum* originating from maize, Cvetnić et al. (2005) established high concentrations of ZEA ranging from 60.000 to 180.000 μg/kg, while Logrieco et al. (2003) observed significantly higher ZEA concentrations (1.500.000 μg/kg).

Results of the quantitative analysis of DON of studied *F. graminearum* isolates showed that maize-derived isolate 699 had synthesised DON with the highest concentration (334.4 μg/g), while the lowest concentrations (14.2 μg/g) were produced by the wheat-derived isolate 866 (Table 1). The comparison of total average concentrations of DON originating from various hosts shows that *F. graminearum* isolates derived from maize synthesised the highest concentrations (85.09 μg/g), while those wheat-derived isolates synthesised DON concentrations of 70.36 μg/g (Table 1). However, previous studies showed that *F. graminearum* isolates derived from wheat had synthesised greater DON concentrations in comparison with isolates derived from maize kernels (Tančić et al., 2015). The greatest variation range in concentrations of this mycotoxin was observed in maize-derived isolates: 17.5 μg/g (isolate 1249) to 334.4 μg/g (isolate 699) (Table 1). On the other hand, this variation in wheat-derived isolates ranged from 14.2 μg/g to 184.6 μg/g. Tančić et al. (2015) established in their studies on synthesis-ability of *F. graminearum* isolates that the span between the minimum and maximum synthesis of toxins was identical for both wheat- and maize-derived isolates in Serbia. Stanković et al. (2008) studied the potential of the synthesis of *F. graminearum* isolates originating from wheat kernels sampled under various agroclimatic conditions in Serbia and established that all isolates had the ability to synthesise DON up to 45.26 μg/g. Contrary to these results, Tančić et al. (2015) recorded significantly lower average concentrations of DON (10.1 μg/g) synthesised by *F. graminearum* isolates. Concentrations of synthesised DON in this study ranged from 14.2 to 334.4 μg/g. Jajić et al. (2007) established similar values of DON concentrations in wheat kernels (from the detection threshold to 465.9 μg/g). When observing DON synthesis-ability in *F. graminearum* isolates derived from maize, Harris et al. (1999) detected a significantly greater variation range of concentrations (160-1302 μg/g).

Table 2. Correlation between pathogenicity and production ability of mycotoxins by *F. graminearum* isolates

Pathogenicity	Mycotoxin			
	DON (μg/kg)		ZEA (μg/kg)	
	maize	wheat	maize	wheat
maize	0.55*		0.49	
wheat		0.53*		0.48

*Statistically significant difference (p<0.05)

The results obtained in the study about pathogenicity of *F. graminearum* isolates on maize ears under field conditions and the qualitative analyses of mycotoxins pointed out to the existence of a statistically significant correlation between isolate aggressiveness and synthesis-ability of mycotoxin DON. However, it was noticed that there was no statistically significant correlation between isolate aggressiveness and ZEA-producing ability of maize- and wheat-derived isolates (Table 2). There are many different data in literature regarding the correlation between isolates pathogenicity and their ability to synthesise mycotoxins (Carter et al., 2002; Mesterházy, 2002; Gilbert et al., 2002; Kuhnem et al., 2015). By studying pathogenicity and chemotypes of *F. graminearum* isolates**,** Carter et al. (2002) established that different chemotypes were equally pathogenic to wheat, while the NIV chemotype was significantly more pathogenic to maize, pointing out to the possibility that the type of produced toxin could affect the degree of isolate pathogenicity, as well as that the plant host could affect the expression of these properties. Mesterházy (2002) observed that the aggressiveness of the species *F. graminearum* and *F. culmorum* depends on the DON synthesis, that is, the ability to synthesise mycotoxins was closely related to the degree of aggressiveness. Furthermore, it was determined that the resistance of wheat cultivars significantly affected the DON synthesis. The same author concluded that the amount of a synthesised mycotoxin was positively correlated with its aggressiveness, while the cultivar resistance had a stronger effect on the mycotoxin synthesis. By analysing 15 *F. graminearum* isolates, Kuhnem et al. (2015) observed that there was a significant correlation between the DON synthesis and aggressiveness of isolates of this species on wheat and maize. Only one isolate did not synthesise DON on wheat and maize kernels, although it expressed pathogenicity in both hosts. The studies performed by the same authors showed that nine of 15 isolates had synthesised ZEA on maize kernels, while this mycotoxin was not detected in wheat kernels. The amount of synthesised ZEA was not correlated with the degree of aggressiveness on maize. Contrary to these studies, Gilbert et al. (2002) studied 15 *F. graminearum* isolates originated from Canada and noticed that the intensity of the disease in wheat was not correlated with the amount of synthesised DON.

Conclusion

Small grains and maize are exposed to numerous diseases, while fusarioses are the most common and most important diseases occurring on these plant species. The harmful effect of the *F. graminearum* is enhanced by the ability to produce metabolites that are toxic to humans and animals. Having sufficient information on all factors that directly or indirectly affect the development of the disease is a necessary prerequisite for successful prevention of damages caused by this pathogenic species. Studies have shown that all observed *F. graminearum* isolates derived from maize and wheat were pathogenic on maize ears. The isolate aggressiveness ranged from 2.11 to 4.99. Results of the quantitative analysis of mycotoxins obtained by the ELISA showed that all studied isolates had ability to synthesise mycotoxins DON and ZEA in the range of 14.2-334.4 μg/g and 1.12-123.17 μg/kg, respectively. A statistically significant correlation was established between the pathogenicity of *F.*

graminearum isolates and the DON synthesis-ability, while there was no a statistically significant correlation between the aggressiveness and ZEA synthesis-ability.

Climate factors together with numerous physical and cultural conditions affect the geographical and seasonal variation of the appearance of toxigenic species, as well as the level of the mycotoxin synthesis. In recent years, global climatic changes have caused variability of agroclimate conditions, which can contribute to the synthesis of higher concentrations of mycotoxins in wheat kernels during the growing season and can cause economic losses in production, as well as an increased risk to human and animal health. The stated reasons indicated the need for continuous monitoring of these toxigenic species in the cereal production.

Abstract

Grain yield of small grain cereals is mostly determined by the number of spikes m^{-2}, number of kernels per spike and kernel weight, which are, therefore, direct yield components. The objective of the study was to assess the effect of mineral fertilisers, particularly phosphorus, manure and liming, on grain yield and yield components in triticale cultivars grown on an acidic soil, and evaluate their interactions. The results confirmed significant differences among cultivars and showed a positive effect of mineral fertilisers, manure and liming on grain yield and yield components in all cultivars. There were significant positive correlations at ($P \leq 0.05$) between grain yield and yield components, as well as among yield components. Grain yield exhibited the strongest correlation with number of spikes per m^{-2}, plant height and number of kernels per spike. Number of kernels spike was very strongly correlated with spike length, kernel weight per spike and main stem weight. Interactions between grain yield and yield components under different agro-environmental conditions serve not only as a guide to making a proper choice of cultural practices but also as a selection criteria in choosing cultivars for less favourable production conditions.

Keywords: *Triticale, correlation, grain yield, yield components*

Introduction

Triticale (*x Triticosecale*) is a cereal crop developed by crossing wheat (*Triticum* sp.) and rye (*Secale cereale*) to combine the positive traits of wheat (yield and quality) and rye (resistance/tolerance to biotic and abiotic stresses). Breeding has mostly improved triticale traits such as nutritional value, earliness, grain fill and grain yield. As the result of its positive characteristics, triticale has become an important crop, with its world acreage (5 million ha) increasing (Đurić *et al.*, 2015). Most triticale cultivars developed in Kragujevac are generally early maturing and highly drought resistant (Milovanović *et al*., 2006). The high tolerance of triticale to arid conditions has also been confirmed by the research conducted in Egypt (Hassan, 2003). Triticale is suitable for regions where wheat and other cereals give low yields, particularly on less fertile and acidic soils, which account for 30–40% of total world soil area (von Uexkull and Mutert, 1995). Acidic soils are deficient in macronutrients, particularly readily available P and increased levels of toxic H and Al ions (Samac and Tesfaye, 2003). In terms of resistance to Al toxicity, there is high variability among species as well as among cultivars within species. A relatively high range of Al resistance has been determined in wheat (de Sousa, 1998) and rye (Aniol *et al*., 1980). Triticale has good tolerance to low pH (about 5.0) and many triticale genotypes have shown better adaptation to acidity in comparison with wheat cultivars (Oettler *et al.*, 2000). Triticale produces satisfactory yields under unfavourable weather conditions (Nožinić *et al.*, 2009) and at high altitudes (Stošović *et al.*, 2010). Triticale exhibits high tolerance to acidic soils and good productive performance on sandy soils (Madić *et al.*, 2013; Đekić *et al.*, 2014). The objective of this study was to analyse

the effect of mineral and organic fertilisation and liming on grain yield and yield components in two triticale cultivars grown on an acidic soil, and determine their correlation.

Material and Methods

A field trial with two triticale cultivars, 'Favorit' and 'KG-20', was conducted on the experimental field of the Secondary School of Agriculture in Kraljevo from 2013 to 2015 (43°43′00′′N, 20°40′60′′E, 198 m altitude). The soil used for the trial was characterised by unfavourable physical properties, a low content of humus and an acid pH (pH_{H2O} = 4.7). In both experimental years, crop rotation was used, with maize as the preceding crop. The trial was established in a randomised plot design with three replications and a plot size of 10 m^2. Seeds were sown mechanically, at a spacing of 12 cm between rows and 3 cm within rows.

Complex NPK fertilisers (N_8: P_{24}:K_{16}), superphosphate (17% P_2O_5) with different amounts of phosphorus (I–0; II–80; III–160; IV–80 kg ha^{-1}) and a top dressing of ammonium nitrate 34.4% N (120 kg ha^{-1}) were used. Phosphorus and potassium fertilisers and one third of nitrogen were incorporated during seedbed preparation. The remaining amount of nitrogen was used for top dressing at the beginning of spring. In addition to mineral fertilisation, "Njival Ca" lime (98.5% $CaCO_3$, 1% $MgCO_3$) was applied in treatment IV. At full maturity, 30 plants were sampled from each plot for analysis of plant height (cm), spike length (cm), kernels per spike, kernel weight per spike (g) and grain yield (kg ha^{-1}). Number of spikes/m^{-2} was determined at the end of the growing season during sampling by counting spikes per m^{-2}. After harvest, grain yield per plot was measured and calculated as yield.

The results were subjected to a two-way analysis of variance (with cultivar and fertiliser as factors), and the significance of differences between means was assessed by the LSD test using SPSS software (1995). The correlation between yield and yield components was expressed by the simple correlation coefficient.

Results and Discussion

The results of the analysis of variance revealed significant differences in the analysed traits between the cultivars and across fertilisation treatments (Table 1). Stem height is mostly determined by the genetic makeup of cultivar, production method and climatic conditions (Kirchev *et al.*, 2012). Stem height in the experimental years showed significant differences, which indicated a significant effect of different rates of phosphorus fertilisers and liming. Significantly higher values for stem height in both years were produced by liming (treatment IV) and increased P rate (treatment III), whereas no differences were observed between the years. Spike length and number of kernels per spike in all treatments showed significant differences in comparison to unfertilised treatment (Table 1). Kirchev *et al.* (2012) found that spike length and number of spikelets per spike are largely determined by genotype. Kernel weight per spike in both years was lowest in the control (treatment without mineral fertilisation), significantly higher after mineral fertilisation, and highest under mineral fertilisation and liming treatments.

The number of kernels per spike and number of kernels per plant are the result of the number of spikelets and number of flowers per spikelet, on the one hand, and fertilisation and seed set success on the other, indicating that the number of kernels is largely dependent on additive and non-additive genetic action (Madić *et al.*, 2014) and environmental conditions (Kirchev *et al.*, 2016; Kirchev and Georgieva, 2017).

Number of kernels m^{-2} was lowest in the treatment without mineral fertilisation, significantly higher in treatment II and treatment III, and highest in treatment IV (treatment with mineral fertiliser and lime). Regardless of the type of fertiliser used, in both years, cv. 'Favorit' had significantly higher values for all traits, except for grain yield in 2014. Differences in grain yield in both years were significant among treatments: the lowest in treatment I, and the

highest in treatment IV. Averaged across cultivars, grain yield increased almost threefold in the first and the second year under liming and mineral fertiliser treatment (regardless of cultivar), compared to the unfertilised control, whereas increased amounts of P (treatments II and III) resulted in an almost twofold increase in grain yield in both years. The response of cultivars to liming was more pronounced than their response to increased P fertilisation. As 'Favorit' exhibited a better response to liming, its yield in treatment IV in both years was higher than that of cv.'KG-20'. Harmoney and Thompson (2005) reported that triticale grown for green forage showed a favourable response to small incremental levels of N and P. Moinuddin and Afridi (2008) also reported that triticale grain yield was positively affected by increasing NP rates up to a level of 200 kg N + 40 kg P ha^{-1}, whereas negative effects occurred with a further increase.

Table 1. Means for stem height (SH), spike length (SL), number of kernels per spike (NKS), kernel weight per spike (KWS), number of spikes m^{-2} (NS) and grain yield (GY), for triticale cultivars under different fertiliser treatments in 2013/14 and 2014/15.

** F –test significant at 0.01; * F –test significant at 0.05; ns –non-significant

The coefficients of simple correlations between grain yield and yield components, as well as those among yield components had positive significant values at $P \leq 0.01$, except between grain yield and spike length ($P \leq 0.05$) (Table 2). Grain yield was most strongly correlated with number of spikes m^{-2}, stem height and number of kernels per spike. Number of kernels per spike was very strongly correlated with spike length and kernel weight per spike. Kozak *et al*. (2007) found that the strength of correlation between grain yield and yield components, and the strength of correlation among yield components cannot be explained by yield structure; therefore, their correlation, as reported, is mostly determined by genotypic factors. In their analysis of 271 triticale lines, Giunta *et al.* (1999) determined that spikes per m^{-2} is a

limiting grain yield component in winter triticale. Mandry *et al*. (1994) and Oettler *et al*. (2000) also observed a strong correlation between spikes m^{-2} and grain yield.

Table 2. Correlation coefficients among grain yield (GY), stem height (SH), spike length (SL), number of kernels per spike (NKS), kernel weight per spike (KWS) and number of spikes m^{-2} (NS)

	SH	SL	NKS	KWS	NS
DK-*SL*	0.80**				
BZK-*NKS*	0.82**	0.89**			
MZK-*KWS*	0.75**	0.81**	0.79**		
BK-*NS*	0.52**	0.60**	0.54**	0.66**	
PZ-*GY*	0.61**	0.38*	0.61**	0.54**	0.71**

*significant at $P \leq 0.05$; **significant at $P \leq 0.01$

The significant positive correlation between number of kernels per spike and kernel weight per spike is consistent with the results of Fischer (1985), who found that number of kernels per unit of biomass is constant for genotypes in a wide range of environmental variation. Wallace and Zobel (1994) reported that the environment modifies the expression of yield components, thus changing grain yield and the relative contribution of yield components to grain yield.

Conclusions

Triticale cultivars 'Favorit' and 'KG-20' exhibited a better response to liming in comparison to increased levels of phosphorus fertiliser, which can be associated with the greater availability of macro- and micronutrients as soil pH increased, i.e. with phosphorus immobilisation in the strongly acidic environment. As 'Favorit' responded better to mineral fertilisation and liming, it produced significantly more kernels per spike and spikes per m^{-2}, and hence larger grain yields, under these treatments in all years, in comparison to cv. 'KG-20'. Significant positive correlations were generally found among yield components as well as between grain yield and yield components, except between grain yield and spike length. Grain yield was most strongly correlated with number of spikes m^{-2}, plant height and number of kernels per spike. In addition to providing guidelines for making a proper choice of cultural operations, the correlation between grain yield and yield components under varied agroenvironmental conditions can serve as a selection criterion for choosing cultivars for less favourable production conditions.

KINETICS OF DRY MATTER CONTENT DURING DRYING OF CV 'ČAČANSKA RODNA' FRUITS

Miodrag KANDIĆ*, Olga MITROVIĆ, Branko POPOVIĆ

Fruit Research Institute Čačak, Kralja Petra I, 9, 32000 Čačak, Serbia
*Corresponding author: kandicm@ftn.kg.ac.rs

Abstract

Drying kinetics of plum fruits can be presented with diifferent drying curves (curves of fruit mass, moisture content on a wet base, moisture content on a dry base…), as well as with appropriate drying rate curves. This paper presents the curve of dry matter content change of the fruits of CV 'Čačanska Rodna' during the drying process. Fruits of the plum cultivar Čačanska rodna taken from the Fruit Research Institute Čačak 'Preljinsko brdo' site have been used for the examination. Tests were conducted using convective procedure in the hot air flow at the constant drying temperature of 90 ºC throughout the experimental drying chamber. Prior to drying experiments, fresh fruit mass, content of stone and dry matter content were determined. Mass share of the stone in the fruit was determined based on the fruit and stone mass. Before the drying process, the fresh plum fruits with pre-defined characteristics were distributed on the trays. Then the trays were placed in a drying chamber with the pre-adjusted drying air temperature. During the drying process, fruit masses were measured on the trays at the respective time intervals, thereby monitoring the kinetic process. It was noted that dry matter content in fruits increased during the drying process and the curves of dry matter content change were suitable for presenting the kinetics of drying process.

Key words: *Convective drying, Drying curves, Dry matter content, Fresh fruit characteristics.*

Introduction

Prunes are the most important dried fruits in the Serbia. In order to obtain dried fruits of high quality (i.e. appropriate appearance, color, consistency, taste and odour), it is important to select suitable varieties for drying (Cinquanta et al., 2002; Mitrović et al., 2013a). Also, it is important to select fresh fruits with adequate technological properties (Kandić et al., 2017).

The process of convective drying is a process of evaporation of water from the fruits with heated air, which is still the most common and the most widespread way of drying plums in Serbia. But this does not mean that the dried fruits of high quality can be obtained by any convective drying process. This is a complex simultaneous process of heat and mass transfer. Heated air simultaneously transfer heat and receive the evaporated water at the same time. Therefore, in order to define the optimal technology of convective drying of the plum, the kinetics of the drying process of plums in experimental laboratory or semi-industrial (pilot-scale) devices are carried out (Barbanti et al., 1995; Newman et al., 1996; Mitrović et al., 2013b). Drying kinetics can be presented by different curves (curves of fruit mass, moisture content on a wet base, moisture content on a dry base…) that represent changes of basic material (plums) physical characteristics by time.

The aim of this study was to determine suitability of curves of the dry matter content changes for displaying the kinetics of the plum drying process.

Material and methods

The tests were carried out in 2016, in an experimental dryer for testing the kinetics of the process of convective drying. The most important segment of this device is the drying chamber with trays (Kandić et al., 2007; Kandić et al., 2014).

As testing material in the experiments, the fruit of the Čačanska rodna variety from the experimental orchard of the Fruit Research Institute Čačak (Serbia), from the locality Preljinsko brdo, was used.

Analyses of fresh plums before the drying process included:

- mass of fresh fruits (g),
- stone ratio (g/g),
- total dry matter (g/g).

Before the start of the drying process, the total mass of fresh plums on every tray was measured. In all experiments, the total mass of fresh fruits on the trays was about 3,500 g.

The experiments were carried out in such a way that the trays were placed in a drying chamber. Temperature of the heated air was 90 °C, before passing through plum layers on the trays. At certain time intervals, during the drying process, the mass of the fruits on the trays were measured and in this way the process kinetics was monitored.

Results and Discussion

Results of 18 experiments were shown in Table 1.

Column [1] lists the experiment labels. The other columns show the values of the following experimental parameters:

- M_0 [g] - Total mass of fresh fruits on the tray (column [2]);
- Number of fruits on the tray (column [3]);
- M_P [g] - Average mass of fresh individual fruits (column [4]);
- G_{Ko} [g/g] - Average mass fraction of the stones in fresh fruits (column [5]);
- G_{SMo} [gSM/g] - Content of total dry matter in edible part of fresh fruits (total dry matter of fresh fruits) (column [6]);

- G_{SMz} [gSM/g] -The total dry matter content in the edible part of the dried fruits (total dry matter of the dried fruits) (column [7]);
- τ_Z [h] - Total duration of the drying process on the tray (column [8]).

By analyzing the values of the characteristics of the fresh fruits shown in Table 1, the following can be noted:

Total mass of fresh fruit on the tray M_0 in all 18 experiments had approximately the same value of 3,500 g (values were from 3,496 g to 3,506 g).

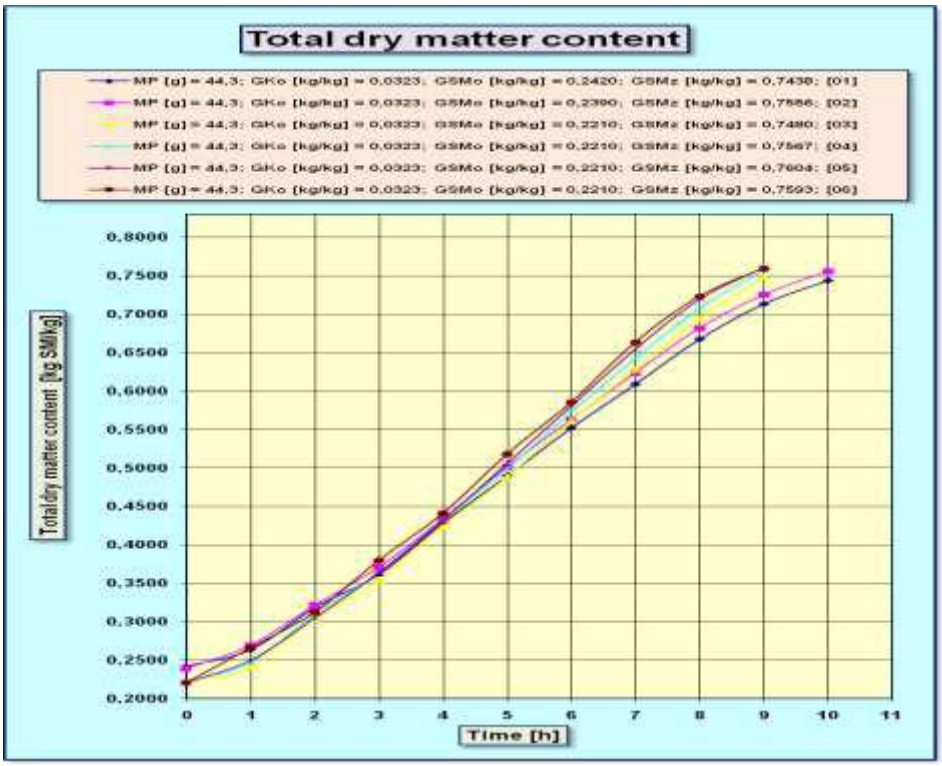
The 18 experiments presented are divided into three groups of 6 experiments.

- The first group contains data for 6 experiments with the same characteristics of fresh fruits. In all 6 experiments 79 fresh individual fruits were distributed on the trays. The average mass of these fruits was $M_P \approx 44.3$ g and the average mass fraction of the stones in fresh fruits was $G_{Ko} = 0.0323$ g/g. The total dry matter content of fresh fruits in 4 experiments was $G_{SMo} = 0.2210$ g DM/g. Only, in the first two experiments of this group the total dry matter content was $G_{SMo} \approx 0.24$ g DM/g.
- The second group contains data for 5 experiments with almost the same characteristics of fresh fruits. In three experiments 82 fresh individual fruits were distributed on the trays. The average mass of these fruits was $M_P \approx 42.7$ g, the average mass fraction of the stone in fresh fruit was $G_{Ko} = 0.0334$ g/g, and the total dry matter content was $G_{SMo} = 0.2350$ g DM/g. In two experiments 80 fresh individual fruits were distributed on the trays. The average mass of these fruits was $M_P \approx 43.8$ g, the average mass fraction of the stone in fresh fruits was $G_{Ko} = 0.0345$ g/g, and the content of the total dry matter was $G_{SMo} = 0.2222$ g DM/g. Only the first experiment in this group had different characteristics of fresh fruits. In that experiment 77 fresh individual fruits were distributed on the tray. The average mass of these fruits was $M_P \approx 45.5$ g, the average mass fraction of the stone in fresh fruits was $G_{Ko} = 0.0332$ g/g, but content of total dry matter was lower than 0.2 g DM/g i.e. $G_{SMo} = 0.1975$ g DM/g.
- In the third group, data for 6 experiments with almost the same characteristics of fresh fruits. In five experiments, the average mass fraction of the stone in fresh fruits was $G_{Ko} = 0.0362$ g/g and the total dry matter content was $G_{SMo} = 0.2321$ g DM/g. In the first two experiments from this group, 85 fresh individual fruits were distributed on the trays. The average mass of these fruits was $M_P \approx 41.2$ g. In the next two experiments 86 fresh individual fruits were distributed on the trays. The average mass of these fruits was $M_P \approx 40.7$ g. In the fifth experiment 87 fresh individual fruits were distributed on the tray. The average mass of these fruits was $M_P \approx 40.2$ g. In the last, sixth experiment in this group 86 fresh individual fruits were distributed on the tray, but with somewhat different characteristics of fresh fruits from others in this group. The average mass of these fruits was $M_P \approx 40.7$ g, the average mass fraction of the stone in fresh fruits was $G_{Ko} = 0.0323$ g/g and the total dry matter content was $G_{SMo} = 0.237$ g DM/g.

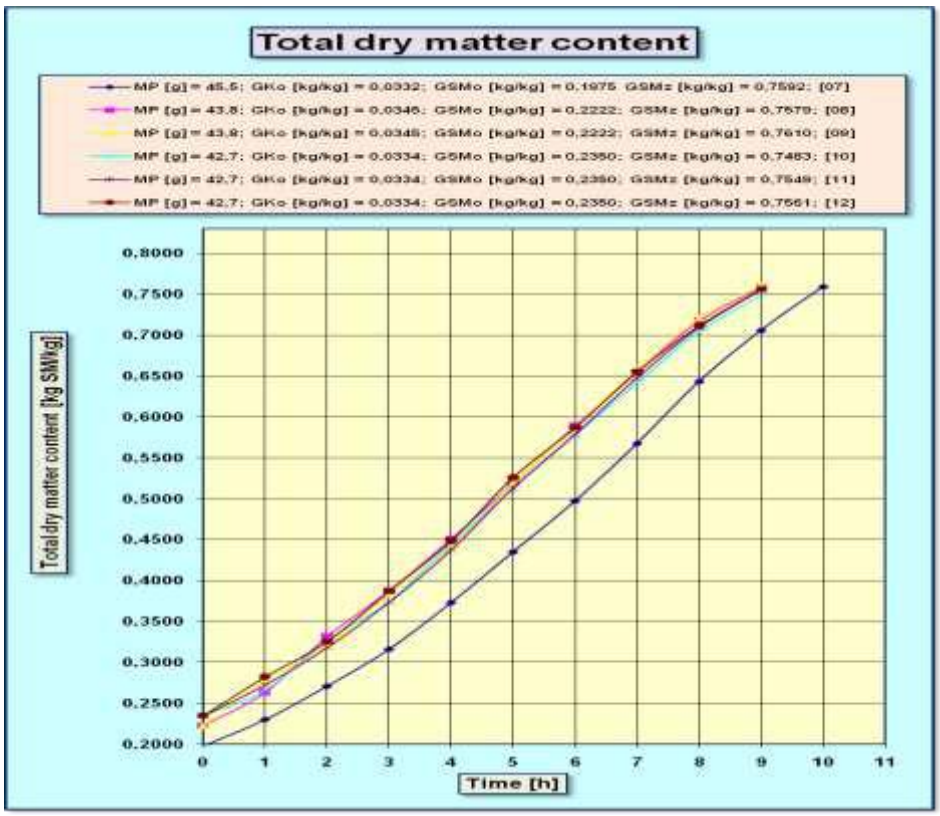
The dependence of the duration of the drying process on the initial characteristics of the plum fruit (average individual mass of fresh fruits, average mass fraction of the stones in fresh fruits and total dry matter of fresh fruits) is shown in Table 1. When the fruits dry up to approximately a constant value of the total dry matter content of GSMz of about 75% and if the initial characteristics of the fruits are similar, then the drying time of the fruit at 90 °C was 9 hours. This is consistent with the results of testing the kinetics of drying plums cv. Čačanska rodna which were obtained in the previous studies (Mitrović et al., 2007; Kandić et al., 2014).

In this work, three graphs of the curves of total dry matter content changes during drying for three groups of experiments are shown. It is interestingly that in 15 experiments there were the excellent matching of all drying curves when the drying time was 9 h. There was a deviation in the first two experiments of the first group and in the first experiment of the

second group, where the drying time was 10 h, which is due to somewhat different values of the initial characteristics of the fruits.



Graph 1: Total dry matter content - group 1



Graph 2: Total dry matter content - group 2

Graph 3: Total dry matter content - group 3

Conclusion

It was concluded that the duration of the drying process depends on the initial characteristics of the plum fruits: the average individual weight of the fresh fruits, the average mass fraction of the stem in fresh fruits and the total dry matter of fresh fruits. If these initial characteristics are approximate values and if the fruits dry up to a near constant value of the total dry matter dry matter, then the drying time of these fruits is the same. It can also be noted that the values of the content of the dry matter of the fruit are increased during the drying process and that the curves of the changes in the dry matter content are suitable for displaying the kinetics of the drying process.

Abstract

The study was carried out to investigate the genotypic and phenotypic variability, heritability and relationship between wheat yield components. A randomized complete block design experiment was conducted, with sixteen wheat genotypes (Dukat, Dunavka, Fundulea 4, Iskra, Jedina, Jugoslavija, Kavkaz, Mačvanka 1, Marija, NS-5804, Pitoma, Poljana, Skopjanka, Tamiš, Vali PKA-7114 and Zvezda), in Novi Bečej (Vojvodina, Serbia), during 2016 and 2017 growing seasons. Grain weight per plant had the highest genotypic and phenotypic variability (15.45 and 20.58%, respectively), while spike length had the lowest ones (5.68 and 6.78%, respectively). High broad sense heritability was observed for plant height (H^2=86.19%) and spike length (H^2=71.73%). Heritability was low in the case of spike weight (H^2=38.82%) and grain weight per spike (H^2=26.56%), which indicates that environmental factors had higher impact on expression of these traits in relation to genetic factors. Path analysis revealed that spike weight and spike length had the highest significant direct positive effect on the grain weight per plant, while thousand grain weight had the highest significant negative effect. The grain weight per spike, number of grains per spike and spike length had a significant indirect effect, through spike weight, on grain weight per spike.

Key words: *Heritability, variability, direct effect, indirect effect*

Introduction

Bread wheat (*Triticum aestivum* L.) is one of the most widely planted crops worldwide and provide about 20% of total food calories for the people of the world (Nukasani *et al*., 2013).

The study of genetic variability and correlation of morpho-agronomic traits with grain yield provides information necessary for successful selection (Ali *et al.,* 2008). It is particularly important to examine the genetic variability of varieties in different agroecological conditions and different soil categories to determine the degree of phenotypic variation and identify the sources of this variability (Petrović *et al*., 2007). Thus, an ideal variety, characterized by high yield or a high value of another desired trait, should exhibit a genetic potential with a low variance value in different environmental conditions (Zečević *et al*., 2008).

It is necessary to separate the total variation into heritable and non-heritable components with the help of genetic parameters, i.e. the genotypic and phenotypic coefficient of variation, and heritability (Paul *et al.,* 2006). Higher heritability values make the selection process more effective, by helping breeders in predicting the interactions of genes in the succeeding generation (Waquas *et al.,* 2014; Saleem *et al.,* 2016). Higher heritabilities indicate that the given trait is under relatively minor influence of the environment (Zerga *et al.,* 2016).

Many researchers have investigated the relationship between yield components and found that knowledge of correlations between traits which determine yield can help in the indirect selection of yield components (Zečević *et al*., 2004a, Hristov *et al*., 2011). In accordance with Rohani and Marker (2016), correlations between yield and its components give a confusing picture due to the mutual relations between the yield components themselves. Thus, mutual

correlations represent only the degree of interaction between given characteristics, while Path analysis quantifies and separates the relationships between yield components into their direct and indirect effects on grain yield (Ashfaq *et al*., 2003).
Path analysis is widely used in plant breeding to determine the nature of the relationship between grain yield and its components, and to determine which yield components with a significant yield effect can be potentially used as selection criteria (Naghavi *et al*., 2014).
The aim of this investigation was to analyze the variability, heritability and direct and indirect effects of yield components on the grain weight per plant. A secondary goal was to determine which traits could be used as yield phenotypic selection markers in a breeding process.

Material and Methods

The experimental material consisting of sixteen diverse wheat genotypes: Yugoslavia, Jedina, Fundulea 4, Iskra, Dunavka, Tamis, Caucasus, Skopjanka, Dukat, Pitoma, Poljana, Marija, NS 58-04, Mačvanka 1, Vali PKA 7114 and Zvezda. Selected genotypes are genetically divergent, which could be used for the development of germplasm in the future plant breeding. The experiment was carried out in a randomized block design with three replications, during two growing seasons (2015/2016 and 2016/2017) in Novi Bečej (Vojvodina, Serbia). The plot size was 2 m^2, where sowing density was 650 grains per m^2. Normal agronomic practices were applied to the experiment throughout the growing season. Ten plants per replication were used for recording plant height (cm), spike length (cm), spike weight (g), number of grain per spike, grain weight per spike (g), grain weight per plant (g) and thousand grain weight (g).
The genetic parameters of variability, estimation of heritability and parameters of variance were computed according to the method suggested by Falconer (1981). The direct and indirect effects of yield components on grain weight per plant were measured by Path analysis as described by Dewey and Lu (1959).

Results and Discussion

The high broad sense heritability of plant height (H^2 = 86.19%) indicates that the analyzed traits had been mostly conditioned by genetic factors, which can help breeders to more easily predict phenotypes of the progeny, based on the genotypes of the parents. This is in agreement with results obtained by Zečević *et al*. (2004a), Petrović *et al*. (2007), Ali *et al*. (2008) and Bhushan *et al*. (2013). The low genotypic and phenotypic coefficients of variation for plant height (GCV = 8.18% and PCV = 8.81%) indicate low variability of this trait, which could be related to the fact that the variation in plant height in European wheat varieties is controlled by the presence or absence of major dwarfing genes (Rht-D1 and Rht-B1) (Würschum *et al*., 2015) (Table 1).
Heritability of spike length was high (H^2 = 71.73%), which is in accordance with results obtained by Ali *et al*. (2008) (76.2%) who noted that the high heritability was contributed by additive gene effects. Thus, selection for this trait can be effective in the early generations. Kotal *et al*. (2010), Rahman *et al*. (2016), Sabbit *et al*. (2017) also found high heritability for spike length. Genotypic and phenotypic variation of spike length was not statistically significant (GCV = 5.68%, PCV = 6.71%), which was confirmed by its small proportion of ecological variance (Table 1).
The low broad sense heritability for spike weight (H^2 = 38.82%) showed that this trait would make the selection process more difficult. Also, Sabbit *et al*. (2017) found low heritability for spike weight. Due to the significant influence of ecological variation, a very significant difference was observed between genotypic and phenotypic variabilities, (GCV = 7.96% and PCV = 11.3%) (Table 1).

Grain weight per spike was a trait with very low broad sense heritability (H^2 = 26.56%). Thus, it would be very difficult to perform effective selection for this trait. This finding is in agreement with results obtained by Zečević *et al*. (2010). The PCV was 12.84%, which was almost twice the GCV (6.67%) (Table 1).

Table 1. Genotypic and phenotypic variance and broad sense heritability of wheat yield components

GWP	13.86	4.67	8.14	6.098	3.47	34.99	15.45	20.58	57.37
TGW	41.26	5.543	9.65	6.002	4.107	4.39	5.69	7.528	57.44

[1]PH – plant height, SL – spike length, SW – spike weight, GWS – grain weight per spike, NGS – number of grains per spike, GWP – grain weight per plant, TGW – thousand grain weight; [2] σ^2_g – genetic variance, σ^2_{ph} – phenotypic variance, $\sigma^2_{g\times y}$ – genptype and phenotype variance, σ^2_E – environmental variance

Heritability in the broad sense for grain number per spike was moderate (63.82%) (Table 1), which is in accordance with results obtained by Zečević *et al*. (2010). Significant GCV and PCV were found for number of grains per spike (10.1 and 12.64%, respectively) (Table 1). Also, Knežević *et al*. (2012) showed a significant phenotypic variability for number of grains per spike, and concluded that it is very advantageous to perform selection for this yield component.

Moderate heritability was recorded for grain weight per plant (H^2 = 57.37%), which confirms a significant proportion of ecological variance within the total phenotypic variance (Table 1). This is in accordance with results obtained by Ali *et al*. (2008), Kotal *et al*. (2010) and Sabbit *et al*. (2017). GCV and PCV for the trait were 15.45 and 20.58%, respectively, showing high variability for grain weight per plant, which, with moderate heritability, could facilitate the selection of parents. The large difference between GCV and PCV indicates a significant contribution of ecological variance to total phenotypic variance (Table 1).

Thousand grain weight exhibited a moderate heritability (57.44%), which is consistent with results reported by Eid *et al*. (2009), who analyzed heritability in arid conditions, while at favorable environmental conditions, they established a higher heritability. Thousand grain weight had low variability (GCV = 5.69%, PCV = 7.53%) (Table 1).

Spike length had a very significant ($p<0.01$) and positive direct effect (0.156**) on grain weight per plant (Table 2). The results obtained are consistent with those reported by Baranwal *et al*. (2012), where they found that spike length had a significant direct and positive effect on grain yield. Path analysis showed that spike length had a significant positive indirect effect (0.229), through spike weight, on grain weight per plant (Table 2). Zečević *et al*. (2004b) found that spike length had the highest positive indirect effect on grain weight per plant through number of spikelets per spike. Spike weight had the strongest direct and positive effect (0.674**) on grain weight per plant, while the indirect effect, through other traits, was not significant (Table 2). These results indicate that spike weight can be a good selection criterion in wheat breeding. Grain weight per spike had a very high positive effect on grain weight per plant, though the greatest influence was contributed by the indirect effect that this

property had through spike weight (0.665). These findings suggest that indirect selection can be made for higher grain weight per spike by selecting plants with a higher average spike weight.

Table 2. Direct and indirect effects of yield components on grain weight per plant

Dependent variable: grain weight per plant									

** $p<0.01$

[1]PH – plant height, SL – spike length, SW – spike weight, GWS – grain weight per spike, NGS – number of grains per spike, TGW – thousand grain weight

The positive influence of number of grains per spike was reflected through the indirect positive effect that this trait had through spike weight (0.545). Therefore, selection for more grains per spike would not necessarily guarantee a higher grain weight per plant. In this case, the selection of plants with a higher number of grains per spike could be done indirectly by selecting for spike weight, all to increase grain weight per plant. Khaliq *et al*. (2004) found that number of grains per spike had a very high and positive indirect effect on grain yield, through spike length. Thousand grain weight had a highly significant and negative direct effect on grain weight per plant (-0.156 **). Kashif and Khaliq (2004) established that thousand grain weight had a significant negative direct and indirect effect on grain yield. Similarly, Nukasani *et al*. (2013) found that thousand grain weight had a negative direct effect on yield, though without statistical significance.

Path analysis showed that plant height had no significant direct or indirect effect on grain weight per plant (Table 2). Nukasani *et al*. (2013) established a positive, but non-significant, direct effect of plant height on grain yield.

Conclusion

High heritability was observed for plant height and spike length. In these traits, ecological variance and genotype × environment interaction made minor contributions to the total phenotypic variance, which could help breeders to predict phenotypes of the progeny based on the genotypes of the parents. Very low heritability was recorded for spike weight and grain weight per spike, which could complicate the process of breeding. Also, significant genotypic and phenotypic variability was observed, especially in grain weight per spike. Spike weight and spike length had the highest significant direct positive effects on grain weight per plant, while thousand grain weight had the highest significant negative effect. Thus, the grain weight per plant could be increased by direct selection for spike weight and spike length. Grain weight per spike, number of grains per spike and spike length had significant indirect effects, through spike weight, on grain weight per spike. Thus, it could be concluded that spike weight

was the trait which contributed most to the increase in grain weight per plant amongst these diverse wheat genotypes.

Abstract

Grapes and grape wine have played an important part in Serbian history, stretching back for thousands of years. Unfortunately, during the last decade the Republic of Serbia had devastating results in regard to the total production of grape. Statistics shown on Statista,astatistic portalshows the global leading grape producing countries in 2016/2017. For that period,China is ranked first and the United Statesfifth in grape production. Serbia is not in the top-ten and the possible reason forthiscan betheshrinking of harvested areas during the last decade. This paper presents an analysis of grape production in the Republic of Serbia, using the index comparison method, i.e. using the statistical data on previous years, comparing them with the data on 2017. The data available on the website of the FAOSTAT statistical database and the Statistical Office of the Republic of Serbia (RZS) were used for the comparison and analysis. The analysis of the data on the period from 2007 to 2017 showed that the total production of grapes and harvesting area was diminishing as the time went on. The biggest harvested area was measured in 2007 and it was 59,068 ha. On the other hand, the harvested area in 2017 was 21,201 ha. The best results in grape production were achieved in 2009. In comparison to 2017, the Republic of Serbia had bigger production of grapes in 2009 by 160%. Theworst results were made in 2014 and the production was around 26% lower than the production in 2017. In the last few years, the harvested area has stopped diminishing and onecan see a little improvement in the production.

Keywords: *grape, production, harvested area.*

Introduction

Serbia is located between 42° and 46° northern latitudes, which is among the most suitable areas for viticulture. Despite the fact that suitable natural conditions for cultivation of grapevines exist in Serbia, grape production is lagging behind the countries with similar conditions (Denda S. and Denda B., 2016). After solving the phylloxericcrisis and renewing vineyards (after 1880),grapevine nurseries were developed in Serbia,producingseedlings by grafting local vines on American grapevine rootstocks. In Serbia, as in all of Central and Eastern Europe in the early nineteen-sixties, high breeding and wide rows, usually 3 x 1 m with 3,333 vines per hectare, were introduced. Over the last twenty years, a quality improvement in viticulture occurred in Serbia, particularly on private properties.A new technology was introduced into viticulture. The spacing between the vines in a vineyard is reduced to 2.2-2.7 m, and the vine spacing within a row is reduced to 0.6-0.8 m, so that the number of plants per hectare is 4000-6000 (Ivanišević *et al*., 2015). According to the method of cultivation, there are plantation and extensive vineyards. Wine varieties are dominant, compared to table ones. Statistical data, after the 2012 census, indicated that there were about 25,000 ha under vines on the entire territory of the Republic of Serbia. Wine grape varieties were grown in Serbia onaround 75.7% of the total vineyard area. The varieties of grapes that were intended for fresh consumption werecultivated on 24.3% of the total area under vines (Ivanišević and Jakšić., 2014). In 2013, vineyards covered 1.0% of the total agricultural area

in the Republic of Serbia. On the basis of statistical data,in the nineteen-eighties, there were 100,000 hectares of vineyards in Serbia, and today there are 22,150 hectares (Ivanišević and Jakšić, 2015; Korać *et al*., 2014). In Serbia, growing organic vineyards is in the initial development, at the surface of around 6 hectares (Vukosavljević*et al*., 2016).The share of grapes in the total amount of agricultural production in Serbia in 2002 amounted to 4.6% (Republički zavod za statistiku, 2007). Later, until 2017, there was a decline in the share of grapes inagricultural production and it was around 2.0%, with slight variations from year to year (Republičkizavod za statistiku,2010).With passing the Law on Plant Protection Products (Zakon o sredstvima za zaštitu bilja, 2009), "Official Gazette of the Republic of Serbia," No. 41/09, plant health and the rights of cultivators were partially aligned with the EU directives and regulations. Large gaps have remained, especially when it comes to implementation and control. Part of the Law on Seeds ("Official Gazette the Republic of Serbia," No. 45/05 and 30/10 – other law), referring to fruits and grapes, is partially harmonized with the EU legislation (ИПАРД програмзаРепубликуСрбијузапериод2014-2020 (2017)).

ProkopijeBolić is considered to be the first Serbianampelographer.Heprovided ampelographic descriptions of 35 vine varieties that were grown in the late eighteenth and early nineteenth centuries in Serbia. Most of these varietiesare extinct;those were native *pontica, balcanica* varieties (Klještanović, 2012; Ivanišević *et al*., 2015). At the end of the nineteenth century, resistant varieties were created, based on the principle that one genotype could combine resistance and quality. So far a greater number of wine and table grape varieties have been created (Klještanović, 2012). The grape assortment in Serbia is divided into the following three groups: native and regional varieties; international and domestic varieties, created varieties (Korać, 2012). In an interview, prof. DjordjePapric said: "When assessing a favorable assortment, one should bear in mind that, out of all grape varieties now we have clones adapted to our climate and they should be grown." (Boarov, 2002)

Grape derivatives are usually wine and brandy, for example, the production of wine in 2013 g. amounted to 45,000 liters (Statistički godišnjak Republike Srbije, 2014). According to the manner of grape use, varieties can be classified into the following groups: wine-grape varieties; alcoholic beverage varieties; table varieties; dried grape varieties; varieties for the production of sweet compotes, marinades, candied fruits, and the like; varieties formakingnon-alcoholic grape juice and concentrates and for the production of colors – teinturiervarieties (Serbian Brandy, 2012).Natural factors make wines in a specific region unique; in wine-making, this term is called *terroir*. These factors include local climatic conditions, the vineyard location (altitude and slope) and soil characteristics. In wine production, fruits are the best when the climate is moderate and provides enough light and nights without frost and porous soil. Vines grow best on soils that are loose, sandy, permeable and rocky (Processing of Raisins and Wine Making, 2000). The same grape varieties can lead to different tastes of wine depending on the place where they were grown. Different soil types and different climatic conditions give products of unique wine styles out of the same grape variety. This phenomenon is called *terroir*. Practically, *terroir* is the connection between the qualitative characteristics of wine and the geographic origin (Ranković-Vasić, 2013). Wine contains alcohol called ethanol. It is present in an amount sufficient to kill microorganisms that cause diseases. It was believed that drinking wine was more useful than drinking water and milk (McGovern, 2007).Wine contains around 85-89% of water, around 10-14% alcohol and less than 1% of fruit acids. Wine characteristics depend on numerous factors, including the grape variety, the place of growing and processing techniques in the winery (Anderson, F. S. and Anderson, D. 1989).The trend in demand for high-quality wines with the geographic origin continues and white wine grape varieties are dominant in modern, young plantations: Chardonnay, Sauvignon, Pinot Blanc, Rhine Riesling, Italian Riesling, Pinot Gris,etc. Currently, vineyards with red wine grape varieties, Cabernet Sauvignon and Merlot, are being

planted to a great extent, and to a lesser extent, vineyards with varieties, Pinot noir, Frankovka and Portugizer (Ivanišević*et al*., 2015). The importance of vines is not only in grapes and grape derivatives. Vines are significant because they can be grown onsoilswhere a number of other crops would not be cost-effective or itwould not be possible to grow them (Burić,1972).In addition to wines and spirits, grapes seeds can be used for the production of oil. The oil content in grape seed samples is relatively low, and it ranges from 7.53 ± 0.07 to 10.88 ± 0.40% on the dry matter. The limiting condition of seed quality, as a raw material for the production of cold pressed oil, is the acid value,which is the highestin samples after distillation(Bjelica*et.al*., 2017).The share of private farms in the total vineyard capacities in the Republic of Serbia in 2006 and 2009 was approximately 92%, and the number of fruit-bearing trees for grapes was about 95% compared to the property of companies and cooperatives (Republičkizavod za statistiku,2007; Republičkizavod za statistiku, 2010).
Based on the research results in 1999, conducted by Simic (1999), it can be noted that a crisis existed in viticulture at the time, where despite favorable climate and soil conditions for the growing of vines, the natural advantages were not utilized. The author (Simić, 1999) points to the extensive nature of production, outdated plantations with nontopicalassortment and low productivity. After this period,after the year 2000, an increase in the production started to happen in orcharding and viticulture, but the livestock production began to decrease (Gulan, 2013).The influence of the soil pH on the quality (taste) of wine is an important factor (Retallack and Burns, 2015).

Material and Methods

Based on the data collected from FAOSTAT for the period from 2007 to 2016 and the 2017 data of the Statistical Office of the Republic of Serbia (Table 1), the index comparison of the total vine production in the Republic of Serbia for the given period was processed. A review of the index comparison for total production is presented in Figure 1.Because of significant changes in harvested area in the last decade there is also a review of the index comparison for total harvested areathat is presented in Figure 2.

Table 1. The area under vines and the production in the Republic of Serbia for the 10-year period (2007-2017) (FAO); * source: RZS (2017)

Year	Grapes - Area harvested (ha)	Grapes – Production (tones)
2007	59068	353343
2008	58324	372967
2009	57540	431306
2010	47366	330070
2011	45804	324919
2012	35719	263419
2013	21201	199955
2014	21201	122489
2015	21201	170647
2016	21201	145829
2017*	21201	165568

Results and Discussion

On the basis of Figure 1, we can conclude that the total vine production in the period from 2009 to 2017 relatively decreased gradually with minor fluctuations during the period from 2014 to 2017.

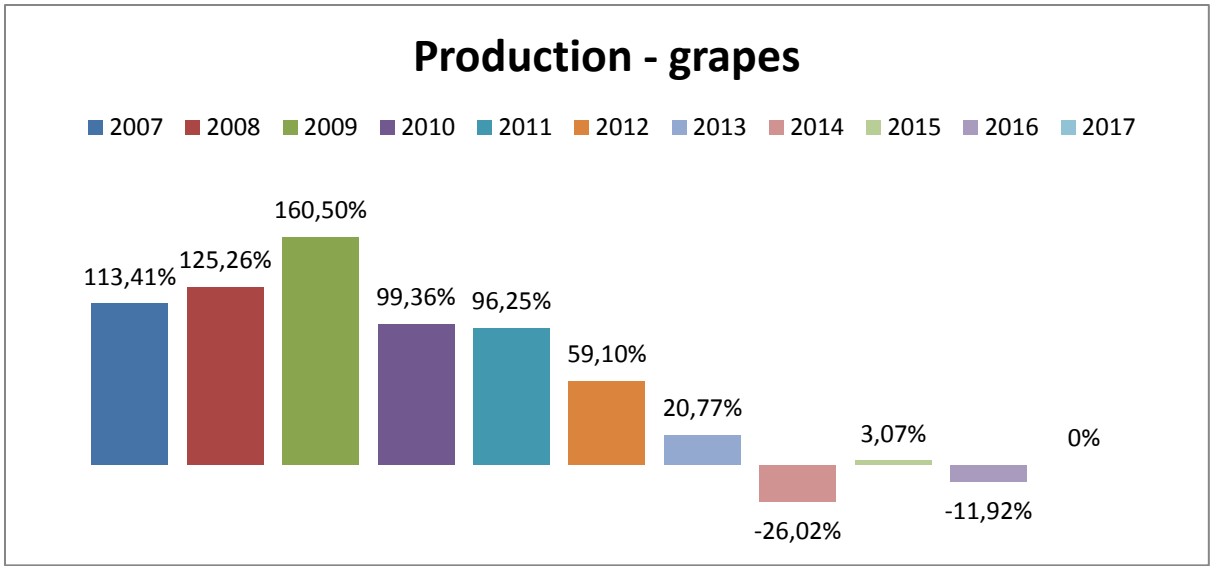

Figure 1. The index comparison of the vine production in the Republic of Serbia for the 10-year period (2007-2017)

The maximum total production was achieved in 2009, when it stood at 431,306 t and when it was higher by 160.5% compared to the total production of the year 2017, which amounted to 165,568 t. The lowest total vine production was achieved in 2014, when it amounted to 122,489 t, which was around 26% lower compared to the total production in 2017.
The total production gradually increased from 2007 to 2009, although there was a slight reduction in the harvested area under vines (Figure 2), and afterwards it was in decline until 2015. In 2015, the achieved production was 29.09% higher than the one in 2014 and 3.07 higher compared to 2017. Thereafter, in 2016, a decrease in the total production by 11.92% occurred in 2016, compared to the production in 2017.
Regarding the harvested areas under vines, based on the FAOSTAT data,Figure 2 was created,presenting an index comparison of the harvested areas in the observed time period.

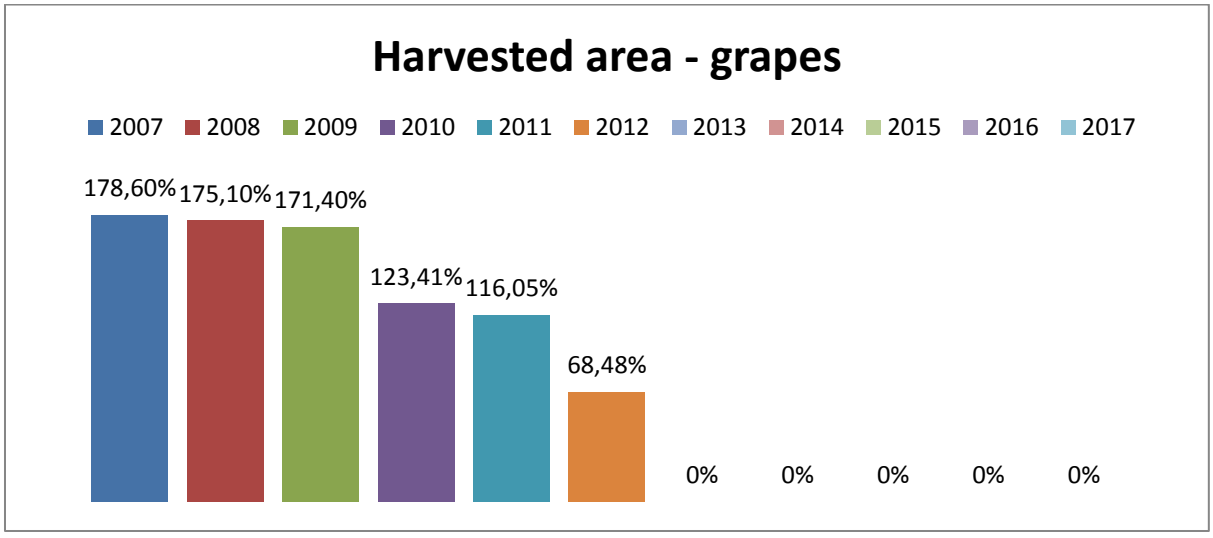

Figure 2. The index comparison of harvested areas under vines in the Republic of Serbia for the 10-year period (2007-2017)

Their clear decreasefrom 2007 to late 2013 can be noted. After this one, there was a period up to 2017, in which neither an increase nor a decrease in thearea under vines occurred. For the observed time period, the Republic of Serbia hadthelargest harvested area under vines in

2007, when it owned 59,068 hectares, which was a larger area by 178.6% compared to 2017. The most visible decrease was noted firstly in 2010 compared to 2009, when the area was reduced by 48%. In 2009, the Republic of Serbia had 57,540 ha under vines, and in 2010 it had 47,366 ha.Thereafter, a more visible decrease in the total harvested area occurred in 2012 compared to 2011, when it was 47.57%. In 2012, the total harvested area was 35,719 ha, while in 2011 it was 45,804 ha. In 2013 (21,201 ha) as compared to 2012 (35.719 ha), the vine areawas smaller by 68.48%, which was also the most visible decrease in the total harvested area under vines during the observed period.

Conclusions

The FAOSTAT results show that the production of vines in the Republic of Serbia from 2009 to 2017 gradually decreased. The maximum total production was achieved in 2009 and the lowest total production of vines was achieved in 2014.When it comes to the harvested area under vines, based on the FAOSTAT data, we can see a decrease from 2007 to 2013. After this, there was a period in 2017, in which there was a stagnation of the area under vines. The Republic of Serbia had the biggest harvested area under vines for the observed time period in 2007, when it owned 59,068 hectares, which was 178.6% a larger area compared to 2017. The most visible decrease was observed firstly in 2010, compared to 2009, when the area was reduced by 48%.

The risk of growing new varieties unadjusted to Serbian agroecological conditions is borne by manufacturers themselves. On Serbian areas favorable for growing vines, with recommended varieties, rootstocks, breeding forms and other information for each of these areas, we can achieve great results in the production of grapes and wine. Since there are exceptional pedological characteristics of the soil, a sufficient number of sunny days, the continental climate, sites of great exposition, there are ecologically clean and healthy areas ideal for vine growing. To intensify viticulture in Serbia, it is necessary to continue with favorable incentives for planting certified seedlings and technology modernization.

THE INFLUENCE OF WEATHER CONDITIONS AND FERTILIZING METHOD ON PLANT HEIGHT AT DIFFERENT CULTIVARS OF WINTER WHEAT

Nadica TMUŠIĆ[1*], Jasmina KNEŽEVIĆ[1], Vera ĐEKIĆ[2], Katerina NIKOLIĆ[1]

[1]University of Prishtina, Faculty of Agriculture, Lešak, Serbia

Abstract

Examinations were performed at stacionary field experiment with fertilization that had been applied for many years (over 30) at the property of Center for Small Grains in Kragujevac (Serbia). The experiments were performed in three years period. The experiment on which examinations have been performed includes also six variants of fertilization: 1) N_0 P_0 K_0; 2) $N_{80.\ 120}$ P_0 K_0; 3) $N_{80.\ 120}$ P_{60} K_{60}; 4) $N_{80.\ 120}$ P_{100} K_{60}; 5) $N_{80.\ 120}$ P_{60} K_0; 6) $N_{80.\ 120}$ P_{100} K_0; 7) $N_{80.\ 120}$ P_0 K_{60}. Individual fertilizers were used: KAN as the nitrogen fertilizer, superphosphate as the phosphate fertilizer, 60% potassium saltas the potassium fertilizer. The experiment included also seven different of winter wheat cultivars: Takovchanka, Ana Marija, KG 100, Lazarica, KG 56S, KG 4 and KG 5. The aim of this work was to examine the influence of various dosages and relation of mineral fertilizers on plant height of different cultivars of winter wheat. The height of plant was the varietal characteristics, but in a great extentlargely depends on the entered fertilizers and weather growing conditions. In the three year average, minimum height of plant for examined varieties of the winter wheat was on the control. The use of fertilizer had a highly significant increase in the height of winter wheat. The biggest height of plants of winter wheat in period of triennial examination, obtained in cultivar KG 4 (80 cm) at NP_1K variant of fertilization, at higher nitrogene dose.

Keywords: *Wheat, Plant Height, Fertilizing Variants, Cultivars*

Introduction

The height of the plant is a varietal feature, but it also depends largely on mineral fertilizers introduced and weather conditions during growing (Malešević, 1989), (Zečević *et al*., 2005). Of all the elements of mineral nutrition on plant height, nitrogen has the greatest influence (Lazović, 1997), as well as other elements of mineral nutrition, phosphorus and potassium (Jevtić and Malešević, 1988). The impact of precipitation and temperature on the plant height depends not only on their quantity, but also on the intensity, but especially on their distribution at certain stages of plant growth and development (Sarić i Jocić, 1993).

According to the research (Pavlović 1997), the share of variety and ecological factors affecting the height of the stem is 48:52% and points out that the factors of the external environment and the genotype/environment interaction significantly influence the height of the stem.

The aim of these tests was to determine the influence of different doses and the ratio of mineral fertilizers to the height of the plant of various varieties of winter wheat.

Material and Methods

The tests were carried out on a stationary field experiment with fertilization, which is performed for many years (over 30) on the property of the Center for Small Grains in Kragujevac (Serbia). The tests were performed in a three-year period as follows: 2005/2006, 2006/2007 and 2007/2008. The experiment in which the tests were performed besides the control includes six fertilization variants: 1) N_0 P_0 K_0; 2) $N_{80,\ 120}$ P_0 K_0; 3) $N_{80,\ 120}$ P_{60} K_{60}; 4) $N_{80,\ 120}$ P_{100} K_{60}; 5) $N_{80,\ 120}$ P_{60} K_0; 6) $N_{80,120}$ P_{100} K_0; 7) $N_{80,120}$ P_0 K_{60}. The individual

fertilizers were used as follows: KAN as nitric, superphosphate as phosphorus and 60% potassium salt as potassium fertilizer. In addition to the mentioned variants of mineral nutrition, seven different Kragujevac winter wheat varieties are included in the experiment: Takovchanka, Ana Morava, KG 100, Lazarica, KG 56 S, KG 4 and KG 5. Takovchanka is a medium early variety, highly resistant to low temperatures. The average height is about 90 cm. Ana Morava belongs to a group of medium early varieties. It has excellent resistance to low temperatures. It is characterized by the medium height. KG 100 is a medium early variety, resistant to low temperatures. Plant height is 70-73 cm. Lazarica is a medium early variety. The height of the stem is about 80 cm. KG 56 S is a medium late variety, extremely resistant to low temperatures. It has a stem of medium height of about 85 cm. KG 4 is a medium early variety of excellent resistance to low temperatures. KG 4 is of medium height, over 85 cm. KG 5 is a medium early variety, of the middle-height of the stem of 82.5 cm. All the investigated varieties in our research were created in the Center for Small Grains in Kragujevac, Serbia.

The surface of the basic experimental plots is 100 m^2 for fertilization with phosphorus and potassium and for fertilization with two nitrogen doses of 80 and 120 kg ha^{-1}, the basic plot was is divided into two sections of 50 m^2 each.

The soil on which the experiment is carried out belongs to the type of vertisol, in the process of degradation (Table 1).

NK		2,24	5,73	4,22	0,16	2,83	23,53

The height of the plant in our research is measured from the soil to the top of the spike.

The experiment was set in a randomized block design with 5 replications. Standard agro-technology was applied to the experiment. Statistical data processing of winter wheat was done using the variance analysis method.

Results and Discussion

The plant height depends on the genetic features of the wheat variety, agrotechnical and climatic conditions during the growing period (Božović, 1993). Weather conditions during the wheat vegetation significantly affect the height of the plants, as well as the overall dynamics of growth and development (Pešić *et al*., 2005), (Mićanović *et al*., 1994).

Based on the data in (Table 2) about mean monthly temperatures and precipitation amounts during our testing we can conclude that the weather conditions were different by the years of testing. The most favorable weather conditions were in the first vegetation period of 2005/06, where the largest total rainfall was recorded with the best distribution according to months.

The temperatures were also optimal for growing wheat, especially during the most important stages of its development. The vegetation period in 2007/2008 was favorable for winter wheat

cultivation, while the most unfavorable weather conditions for growing winter wheat were in the second year of testing.

In the three-year average, the lowest plant height of the varieties examined was in the control. The use of fertilizers resulted in a significant increase in the height of winter wheat (Savić, 2009) (Table 3).

Using only N the plant height increased by 19.72 cm, which was a significant increase in relation to control (Savić *et al*., 2007). The addition of P and K fertilizers (NPK variant) resulted in a significant increase of plants compared to the control and N fertilizer variant (Jaćimović *et al.*, 2012). The plant height on all fertilized variants, except for NP_2K, was significantly higher at higher than lower nitrogen doses.

Using only N the plant height increased by 19.72 cm, which was a significant increase in relation to control (Savić *et al*., 2007). The addition of P and K fertilizers (NPK variant) resulted in a significant increase of plants compared to the control and N fertilizer variant. The plant height on all fertilized variants, except for NP_2K, was significantly higher at higher than lower nitrogen doses.

The varieties on a three-year average showed certain differences in this property, which were naturally caused by differences in their genetic constitution.

The varieties of winter wheat achieved a very different plant height with the same varieties of mineral nutrition. The highest height of the cultivars was Takovchanka (72,31 cm) and KG 4 (71,31 cm), and the difference in height between these two varieties was not significant.

The lowest variety was KG 100 (57.90 cm), which had a significant decrease in plant height compared to all other varieties examined. The highest plant height in the three-year experiment period was achieved by KG 4 (80 cm) on fertilizer variant NP_1K at a higher nitrogen dose.

Conclusions

The obtained results show that the use of mineral fertilizers had a positive effect on the height of plants in almost all varieties of fertilization and in all wheat varieties examined. The plant height on all fertilized variants, except for NP_2K, was significantly higher at higher levels than at lower nitrogen doses. The greatest height had the varieties Takovchanka (72.31 cm) and KG 4 (71.31 cm), and the difference in height between these two cultivars was not significant. The lowest variety was KG 100, which had a significant decrease in plant height compared to all other varieties examined. The greatest plant height in the three-year experiment period was achieved by KG 4 (80 cm) at fertilizer variant NP_1K at a higher nitrogen dose.

Abstract

Aboveground biomass of wheat is considered as one of the most important crop parameters and correct estimation of aboveground biomass can help improve crop monitoring and grain yield prediction. Remotely sensed vegetation indices such as NDVI (Normalized Difference Vegetation Index) represent one of the most promising tools for application in field phenotyping with potential to provide complex information on different traits of wheat. The objective of this study was to evaluate the potential of different NDVIs derived from field reflectance measurements in identification of a specific growth stage in which proximally or remotely sensed data showed the highest correlation with aboveground biomass and grain yield of 24 winter wheat genotypes. The NDVI was determined using an integrated proximal sensor GreenSeeker (NTech Industries Inc., Ukiah, California, USA) and hyperspectral camera (Ximea Corp., Lakewood, CO USA) at four growth stages of wheat: full flowering, medium milk, early dough and fully ripe. The hyperspectral NDVI indices were calculated from two-band combinations between red (600-700 nm) or far-red (700-750 nm) and near-infrared (756-955 nm) regions. Highly significant correlations were found between different NDVIs and both examined traits at medium milk growth stage, with r values of up to 0.69. The strong positive relationship implies that medium milk stage is optimal for wheat traits assessment in semiarid or similar growing conditions. The overall results indicated that hyperspectral camera provided alternative spectral combinations for different NDVIs which could be successfully used in assessing aboveground biomass and grain yield of a large number of wheat genotypes.

Introduction

Being adapted to a broad range of latitudes, temperatures, water regimes and nutritional levels, wheat is one of the most widely grown crops and the future productivity of wheat will arguably have more influence on global food security than any other crop (Reynolds et al., 2012a). Beside of high potential for yield of current wheat cultivars, weather conditions are becoming increasingly unstable due to climate change and grain yields of wheat fluctuate more widely from year to year (Hristov et al., 2012). Since that the pressure put on modern crop production to maximize the yield and minimize the inputs, timely monitoring of crop growth status early in the growing season could be of vital importance for in-season site-specific crop management, especially in regions characterized by climatic uncertainties (Henik, 2012). Large agricultural lands are usually monitored using proximal and remote sensing technology, which allows for instantaneous data acquisition over vast areas (Kostić et al., 2016). Recent studies suggest that remote sensing technology possesses a great potential for estimation of yield and yield related traits, both in precision farming, as well as in large breeding programs (Duan et al., 2017). Agricultural remote sensing is based on canopy light

reflectance indices, which rely on the fact that plants absorb the light at specific wavelengths associated with specific plant traits. These indices could provide large-scale evaluation of germplasm in a rapid and nondestructive manner (Reynolds et al., 2012b; Araus and Cairns, 2014; Morgunov, 2014). Among various vegetative indices, Normalized Difference Vegetation Index (NDVI) is one of the most widely used for crop monitoring, since it is related to leaf development, amount of chlorophyll, amount of photosynthesis, stay-green traits, grain yield and aboveground biomass of wheat (Lopes and Reynolds, 2012). Based on the principle that green vegetation strongly absorbs solar radiation in the red (R) part of the visible electromagnetic spectrum, while strongly reflecting radiation in the near-infrared (NIR) region, NDVI is defined as the difference between the red and near-infrared reflectance divided by their sum (Tucker, 1980). GreenSeeker is the one of the most widely used active hand-held sensors for measuring NDVI due to its invariance to light conditions and the time of day, but limited by its use of only two central wavelengths (Yao et al., 2013). Reflectance in visible and near-infrared regions is strongly dependent on both structural and biochemical properties of the canopy, varies with the growth stage and environmental conditions (Kumar et al., 2001). Hence, it is a challenge to develop a unique and optimal two-waveband combination for NDVI exclusively sensitive to targeted grain yield traits. Hyperspectral data could provide extensive information about plants and can serve as a basis for finding the most indicative wavebands for assessment of targeted crop parameters (Kaur et al., 2015). Therefore, the present study was carried out with two main objectives. The first objective was to find the optimal combination of hyperspectral wavebands in R and NIR regions, for aboveground biomass and early grain yield assessment of 24 winter wheat genotypes. The second objective was to determine the specific growth stage where the correlation between the yield traits and NDVI acquired by GreenSeeker sensor and hyperspectral camera is highest and therefore the most suitable for use in both proximal and remote sensing.

Material and Methods

The present study was carried out at the experimental field of the Institute of Field and Vegetable Crops (45°19′51′ N, 19°50′59′ E) in Novi Sad, Serbia, in typical semiarid conditions, during the 2015–2016 growing season. The experimental material was comprised of 24 winter wheat (*Triticum aestivum* L.) genotypes, namely, Ubavka (G1), Matuška (G2), Javorka (G3), Brazda (G4), Efrosinija (G5), Doroteja (G6), Obala (G7), Vlajna (G8), Kala (G9), Mila (G10), Azra (G11), Nafora (G12), Pudarka (G13), Ljubica (G14), Petrija (G15), Futura (G16), Ilina (G17), NS 40S (G18), Zvezdana (G19), Simonida (G20), Rapsodija (G21), Renesansa (G22), Evropa (G23) and Pobeda (G24). The cultivars were sown in 2 m long rows with 20 cm of inter-row spacing and 10 cm spacing between plants in the row. The trial was sown in a randomized block design, with three replications. Examined cultivars were grown using common agronomic practice. Meteorological data, values of temperature and precipitation throughout the season were obtained from Rimski Šančevi Meteorological Station, located near the experimental field (Table 1). At the stage of full maturity, grain yield (t ha^{-1}) of 24 winter wheat genotypes was estimated, while plants in one square meter of each genotype were harvested from the experimental plots individually to record aboveground biomass (g m^{-2}). For each of the 24 winter wheat genotypes NDVI was measured at four different growth stages: full flowering (BBCH 65), medium milk (BBCH 75), early dough (BBCH 83) and fully ripe (BBCH 89). For NDVI measurements, the GreenSeeker handheld (NTech Industries Inc., USA) proximal sensor and Ximea hyperspectral camera xiSpec MQ022HG-IM-SM5X5-NIR (Ximea Corp., USA) were used.

GreenSeeker, as an active hand-held sensor, emits light and measures the reflectance at 660 nm (R) and 770 nm (NIR) (Tremblay et al., 2009). In-field reflectance measurements were taken by holding GreenSeeker sensor about 60 cm horizontally above the crop canopy and scanning the central part of each wheat plot. For each plot, 10 NDVI readings were collected and averaged to obtain a single value per plot. Hyperspectral camera was mounted at a height of 1 m above canopy on a mobile tripod, which corresponded to an image area of 2 m^2 while the spatial resolution was 0.5 × 0.5 mm per image pixel. Its output was consisted of 66 images, each corresponded to one channel between 600 and 955 nm. As the pixel values are proportional to the existing amount of sunlight, each image was calibrated using Sphere Optics Zenith reflectance sheet. For calibration and calculation of NDVI was used MATLAB (MathWorks Inc., US). As NDVI requires measurements in RED and NIR domains, candidates for the red domain were hyperspectral channels in visible red (600–700 nm) and far-red (700–750 nm) part of the spectrum, while candidates for NIR channel were hyperspectral channels between 756 nm and 955 nm. This gave the aggregate of 3 (red), 22 (far-red and near-infra red) and produced 66 different NDVI indices. The NDVI measurements from both instruments were made close to noon, between 10:00 am and 2:00 pm on sunny, cloud-free days when the plant canopy and soil surface were dry. Pearson correlation coefficient (*r*) was used as a measure of correlation of NDVI with aboveground biomass and grain yield. Besides observing the correlation based on absolute NDVI values, the relationship between the yield traits and the decline in NDVI between BBCH 65 and BBCH 75, BBCH 83 and BBCH 89 was analysed. The relative decline (Dj) in NDVI served as a measure of magnitude of reduction in NDVI from BBCH 65 to BBCH 75, BBCH 83 and BBCH 89, calculated as follows:

$$\mathrm{Dj} = \frac{\mathrm{NDVI_i} - \mathrm{NDVI_j}}{\mathrm{NDVI_i}} \times 100\%$$

where *i* present NDVI measured at BBCH 65 growth stage of wheat, while *j* presents NDVI measured at BBCH 75, BBCH 83 and BBCH 89 growth stage of wheat. In this way we introduced three relative decline measures: D1, D2 and D3, respectively. All statistical analyses were carried out using software STATISTICA, version 13 (StatSoft Inc., USA).

Results and Discussion

The presented results revealed wide range between the minimum and maximum values for observed traits of wheat and the greatest values varied on overall basis. The overall mean values of aboveground biomass of the 24 winter wheat genotypes varied from 300 g m^{-2} for genotype G8 to 700 g m^{-2} for genotype G10. The mean grain yield values varied from 9.2 t ha^{-}

[1] for genotypes G8, G15 and G21 to 11.2 t ha^{-1} for genotype G9. In respect of NDVI values, the results showed that maximum values of NDVI were observed during BBCH 65, when photosynthesis was at the highest point and the leaf area was largest. Through the later growth stages, NDVI values gradually declined reaching the minimum values at BBCH 89. In chronological order, the sensor GreenSeeker based NDVI score ranged from 0.61 to 0.72, 0.40 to 0.61, 0.24 to 0.36 and 0.15 to 0.20 at BBCH 65, BBCH 75, BBCH 83 and BBCH 89 stage of wheat, respectively (Table 2). These results indicated that through the process of senescence toward the end of the season, reflectance of visible wavelengths increases and reflectance of NIR decreases as a consequence of less absorption of visible light in the leaves (Reynolds et al., 2012b; Sultana et al., 2014). The variability of NDVI throughout the genotypes was lowest at the BBCH 65, because the NDVI was mainly affected by saturation effects, which is well known at high crop densities (Erdle and Schmidhalter, 2013). Since that all observed wheat genotypes showed similar and the largest NDVI values at BBCH 65, it becomes clear that this growth stage could not prove to be indicative for aboveground biomass and grain yield assessment. With respect to NDVI values derived from hyperspectral imagery, the results show that two-band combinations respond in different manner to variations in yield traits, but the mean values displayed the same tendency as the GreenSeeker based NDVI values (Table 2). With respect to the association between grain yield and aboveground biomass of wheat it was observed the strong positive relationship (r = 0.88**). Positive relationship between grain yield and aboveground biomass of wheat is mandatory for a system intended to predict yield traits early in the season by assessing the canopy growth (Marti et al., 2007). The strong positive relationship between the grain yield and aboveground biomass of wheat (r = 0.88**) suggested that higher biomass production during the green up stage, particularly during the grain filling period have an advantage for the yield increase in wheat because translocation of assimilates from the vegetative to generative parts of a plant contribute significantly to yield. Significant positive association between aboveground biomass and grain yield of wheat has been confirmed by several researchers (Bogale and Tesfaye, 2016). In present study a high and significant positive correlation between grain yield and aboveground biomass of wheat was observed, which justified approach of predicting the yield by measuring NDVI of the canopy. With respect to the association between measured traits and NDVI from both devices and all hyperspectral two-waveband combinations, the result revealed that the significant and positive association was observed at the medium milk stage of wheat. The GreenSeeker based NDVI showed the correlation of 63%** with aboveground biomass and 58 %** with grain yield. Positive, but not significant correlations were observed at BBCH 83, while the correlations in the stages BBCH 65 and BBCH 89 were lower or even negative with none of them being significant. It can be noted that in aboveground biomass assessment, the NIR wavelength used by GreenSeeker (770 nm) was the optimal one for hyperspectral NDVI, as well, while the R wavelength was slightly longer (674 nm instead of 660 nm). The optimal R wavelength for grain yield prediction remained the same, while the optimal NIR wavelength changed to 909 nm (Fig. 1). Beside of significant positive correlation between NDVI and both traits found at BBCH 75, it was also observed that wheat genotypes which displayed high NDVI values at BBCH 75 tended to have high yield, as well as aboveground biomass. This indicates that the delay in senescence extends the grain-filling period and increase grain yield (Hawkesford et al., 2015). This result agrees with the previous findings of several researchers (Morgounov et al., 2014; Gonzalez-Dugo et al., 2015). Since that optimal stage for measuring NDVI depending on the germplasm and environmental conditions, contradictory findings have been reported.

Table 2. The mean values of aboveground biomass, grain yield, best selected NDVI and magnitude of reduction in NDVI from BBCH 65 to BBCH 75 of 24 winter wheat genotypes

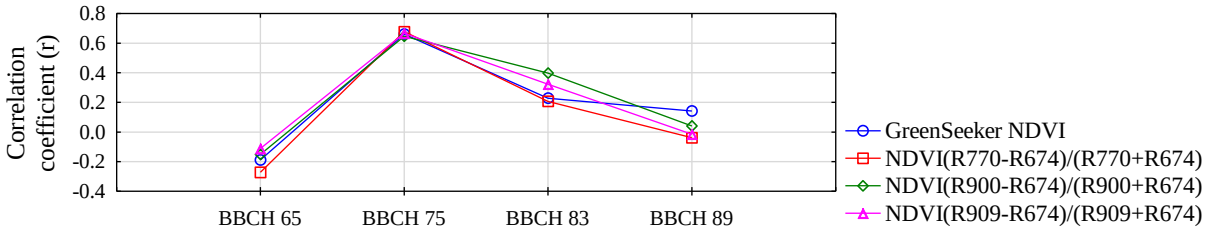
[a]G: Wheat genotypes, [b]GY: Grain yield t ha^{-1}, [c]AB: Aboveground biomass g m^{-2}, [c]D1: Relative decline, reduction in NDVI from BBCH 65 to BBCH 75 for GreenSeeker based and hyperspectral NDVI measured at (R770-R674)/(R770+R674), (R900-R674)/(R900+R674) and (R909-R674)/(R909+R674), respectively (%).

Contrary to these results, previous studies demonstrated that grain yield can be estimated at earlier stages, such as stem elongation and booting stage (Marti et al., 2007; Kaur et al., 2015). The contrasted and variable climate could explain the inability to estimate yield before grain filling, as this period is critical for yield formation, as well as under most conditions 90–95% of the carbohydrate in grain is derived from carbon dioxide fixation after flowering stage (Gonzales-Dugo, 2015). With better growing conditions the grain-filling period extended and the amount of available nutrients increased, the grain achieves a higher yield. Although, the average temperatures during grain filling in early June was 22.6°C, frequently short periods (3–5 days) of hot and dry weather were reflected in NDVI, as well as in grain yield losses. In the stage of full maturity, significant correlation between both traits and NDVI was not observed since in this stage canopy dries out and NDVI drops to minimum.

a)



b)

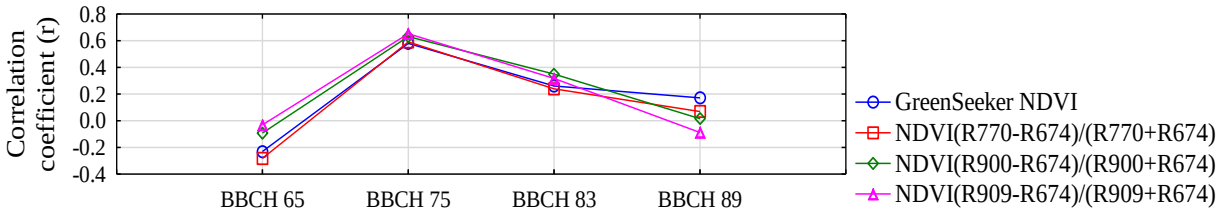


Figure 1. Pearson's correlations coefficients (r) obtained between the best selected NDVI and aboveground biomass (a) and grain yield (b) of wheat at 4 growth stages: BBCH 65, BBCH 75, BBCH 83 and BBCH 89

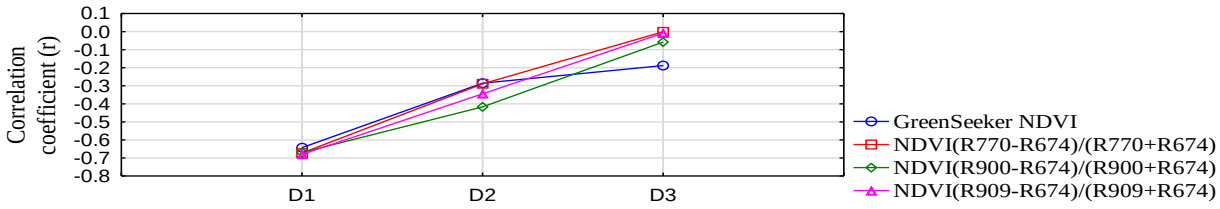
Besides the positive and significant correlation between the absolute NDVI and examined traits at BBCH 75, the significant negative correlation between reduction in NDVI from BBCH 65 to BBCH 75 and both traits was observed (Fig. 2). NDVI values acquired by both devices displayed similar tendency as they both showed the sharpest decline between BBCH 65 and BBCH 75 and expressed the greatest negative correlation with the examined traits. The relative decline displayed the largest, significant negative correlation with the trait aboveground biomass (r = -0.66**) for GreenSeeker based and hyperspectral NDVI (r = -0.71**). The largest significant negative correlation for GreenSeeker based (r = -0.60**) as for hyperspectral NDVI (r = -0.66**) with grain yield was also observed (Fig. 2). Considering this correlation, hyperspectral camera generally outperformed GreenSeeker sensor, by 5% in aboveground biomass prediction for wavelengths (674 nm – 770 nm) and by 7% in grain yield prediction, for wavelengths (674 nm – 909 nm). The magnitude of reduction in NDVI from BBCH 65 to BBCH 75 proved to be different for genotypes and showed a strong negative correlation with measured traits. Based on the magnitude of reduction in NDVI from BBCH 65 to BBCH 75, wheat genotypes G9, G6 and G10, which displayed the lowest reduction (10.8, 11.3 and 14.1 %), could be considered as genotypes with the highest potential for aboveground biomass and grain yield. Corresponding reduction from 44.4, 32.4 and 31.0 % indicated that wheat genotypes G8, G15 and G21 could be considered as genotypes with lower aboveground biomass and grain yield, as seen in Table 2. These results revealed that with progressing senescence, when the temperatures were higher, the quality of differentiating cultivars increased and with certain exceptions, high grain-yielding wheat cultivars maintained higher NDVI during the BBCH 75 than in other stages. A slow decline in NDVI

during the BBCH 75 of certain genotypes as a consequence of delayed senescence increased the wheat grain yield.

a)



b)

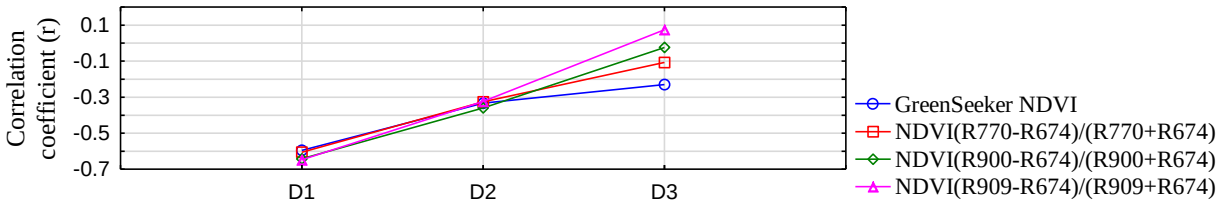


Figure 2. Pearson's correlations coefficients between the values of relative decline of best selected NDVI and aboveground biomass (a) and grain yield (b), where D1 present relative decline in NDVI from BBCH 65 to BBCH 75, D2 relative decline in NDVI from BBCH 65 to BBCH 83, D3 relative decline in NDVI from BBCH 65 to BBCH 89

Conclusions

Reliable estimation of aboveground biomass and grain yield of winter wheat based on NDVI is attained measuring during the medium milk stage. Besides observing absolute values of NDVI in different growth stages, observing the change in NDVI throughout the stages may be very indicative. With certain exceptions, high yielding wheat cultivars maintained higher NDVI during the BBCH 75 than in other growth stages. Furthermore, NDVI acquired with hyperspectral camera was found to be more indicative than NDVI acquired with GreenSeeker sensor since it provides additional waveband combinations for NDVI more sensitive to examined traits. The findings of this study give promising results which can be used as a basis for development and improvement sensing devices with alternative spectral combinations which could be successfully used in assessing important traits of winter wheat.

Acknowledgments

The authors express their appreciation to the Autonomous Province of Vojvodina for providing financial support for this research under project: "Sensor technologies for integrated monitoring of agricultural production".

Abstract

Every year, the Maize Research Institute, Zemun Polje, Belgrade, Serbia organizes the strip trials in a great number of locations throughout Serbia, in order to establish a proper regional distribution of hybrids and to select commercial maize hybrids best adapted to particular production regions. These trials are usually organized in approximately 50 locations per year and they cover all major regions of maize growing in our country. In addition, in 10-12 locations every year, the trials are set up not only with commercial hybrids, but with newly developed hybrids with good traits that have shown promising results in the process of their releasing. The trials were set up to check and compare values of newly developed hybrids with already existing commercial hybrids and to select new hybrids for future production and commercialization. The production value of new hybrids has to be higher than the value of current commercial hybrids within the same maturity group. The results, obtained in 37 locations in the 2014-2017 period, are presented in the present paper. Based on gained four-year results, the medium early maturity hybrids ZP 366 and ZP 388 were selected for commercialization, as they had results better than the commercial hybrid ZP 341.

Key words: *commercial maize hybrids, new hybrids, strip trials*

Introduction

Maize is the most important field crop in Serbia. It has various purposes in nutrition of humans and animals and is a very important factor in the export of agricultural products (Pavlov *et al*., 2011). There are several different regions of maize production in Serbia and each of them is characterized by different agro-ecological conditions. Northern part of the country is more suitable for intensive maize production, while production in central and southern part is more extensive, due to drier and harsher climate and harder soil types (Camdzija *et al*., 2013). Maize breeding program in Maize Research Institute Zemun Polje was established more than 70 years agoand more than ZP 700 hybrids were developed and registered in Serbia so far. Each season 10-15 new ZP hybrids have been registered in Serbia. Every year, the Maize Research Institute, Zemun Polje organizes the strip trials in a great number of locations throughout Serbia, in order to establish a proper regional distribution of hybrids and to select commercial maize hybrids best adapted to particular production regions. These trials are usually organized in approximately 50 locations per year and they cover all major regions of maize growing in our country. In addition, in 10-12 locations every year, the trials are set up not only with commercial hybrids, but with newly developed hybrids with good traits that have shown promising results in the process of their releasing. The trials were set up to check and compare values of newly developed hybrids with already existing commercial hybrids and to select new hybrids for future production and commercialization. The production value of new hybrids has to be higher than the value of current commercial hybrids within the same maturity group.In addition to high productivity, it is important that new hybrids have good stability parameters, which means that hybrids have good performances in both, optimal and poor agro ecological conditions (Babic *et al*., 2006, Stevanovic *et al*., 2011). The aim of this work was to evaluate performances and select new maize hybrids for further commercialization, based on the results obtained in strip trials.

Material and methods

Twelve maize hybrids from FAO groups 300-600 were evaluated at 37 locations in strip trials from 2014-2017. Testing locations represent the most important growing regions in Serbia. Plot size per each hybrid was 0.1 ha. Sowing and harvesting were performed mechanically. Grain yield (GY) is calculated to the moisture content of 14%. Planting densities applied in this study were 69500 plants/ha^{-1} for hybrids FAO 300-400, 65000 plants/ha^{-1} for FAO 500 and 59500 plants/ha^{-1} for FAO 600. Majority of the hybrids used in this study are widely grown, commercial maize hybrids, but also new, promising maize hybrids were included in trials. Hybrids belonging to FAO 500-600 used in this work are already commercial, but in FAO 300-400 only ZP 341, ZP 427 and ZP 434 are commercial, while other hybrids are selected according to the promising results during registration period.

Stability parameters were estimated by model proposed by Eberhart and Russel (1966). As described by this model, the behavior of the cultivars was assessed by the model $Yij=m+biIj+dij+eij$, where Yij = observation of the i-th (i =1,2,..., g) cultivar in the j-th (j=1,2,...n) environment, m=general mean, bi=regression coefficient, Ij=environmental index obtained by the difference among the mean of each environment and the general mean dij the regression deviation of the i-th cultivar in the j-th environment and eij=effect of the mean experimental error (Scapim *et al*., 2000).

Regression coefficient (bi) measures the response of genotypes to environments. When bi=1 there is average stability and adaptability to both poor and good environments, when bi>1 genotypes give above average stability only in good environment. Whereas, when bi<1, it indicates genotypes adaptation to poor environment (Aremu *et al*, 2009).

Results and discussion

Average grain yields and moisture content of the examined hybrids in each year of testing are presented in Table 1.

Table 1: Average grain yields and moisture content of the examined hybrids during 2014-2017. period

Average	11093	18.2	7957	17.0	10398	17.9	7281	15.1

In 2014 and 2016. average grain yields were higher compared to other two years of testing, due to enough quantity and good distribution of precipitations. On the other side, 2015. and especially 2017. were characterized by lack of precipitation and very high temperatures during pollination and grain filling period and obtained grain yields were lower. For this study we used results only from five testing locations in 2017, since results from some locations were not useful due to extreme weatherconditions. In order to evaluate yield stability of maize hybrids it is desirable to test hybrids in optimal, but also in poor agro ecological conditions.
In FAO 300, hybrid ZP 366 overyielded ZP 341 in all four seasons of testing. In 2014., 2015. and 2017. grain yield of this hybrid were slightly higher than ZP 341, while the best results it obtained in 2016. Hybrid ZP 388 had the highest grain yield among all hybrids from FAO 300 in 2014. and 2016., which were very suitable for maize production. On the other side, in 2015. and 2017, which were more dry, it had lower yield compared to ZP 341 and ZP 366.
When it comes to the hybrids FAO 500-600, hybrid ZP 606 had the highest yield in 2014., 2015. and 2016., while ZP 600 has the highest grain yield in 2017. In these maturity groups also some new hybrids were examined, but none of them were tested during the 2014-2017 period, therefore results are presented only for the hybrids which were tested in all four years of testing.
In Table 2 average grain yields based on the results from 37 locations during the 2014-2017 as well as stability parameters are presented.

Table 2: Average grain yields, moisture content and stability parameters for the four year period of testing (Source: Author's elaboration based on obtained results from strip trials)

Hybrid	GY kg/ha	Moisture %	Rank GY	bi	Rank bi
ZP 333	8850	16.3	12	0.9533	8
ZP 341	9210	16.6	11	0.9920	3
ZP 366	9378	16.8	7	1.0101	5
ZP 388	9367	17.1	8	1.0089	4
ZP 4007	9272	16.7	10	0.9987	1
ZP 427	9564	16.5	5	1.0302	7
ZP 434	9325	16.6	9	1.0044	2
ZP 555	9410	18.2	6	1.0135	6
ZP 560	9941	17.7	2-3	1.0707	10
ZP 600	9941	18.3	2-3	1.0707	10
ZP 606	10427	18.9	1	1.1231	11
ZP 666	9821	18.7	4	1.0578	9
Average	9542	17.4			

Medium-early matured hybrids had *bi* value lower than 1, which means that they have better adaptability to poor environments, while late maturity were better adapted to good environments and had *bi* value higher than 1. Similar results were reported by Camdzija *et al.*, 2012, who also found that late maturity hybrids have better adaptability to good environments.
When it comes to the grain yields of medium-early maturity hybrids, in FAO 300 hybrid ZP 366 had the highest grain yield (9378 kg/ha), followed by ZP 388 (9367 kg/ha). Both hybrids had higher yield than standard commercial hybrid ZP 341, so they can be recommended for further commercialization. The most stable hybrid was ZP 4007, but on the other side this

hybrid had yield at the same level as check hybrid ZP 434. Hybrids ZP 434, ZP 341, ZP 388 and ZP 366 also showed above average stability. The most unstable hybrids were ZP 606, ZP 600 and ZP 560.On the other side, three unstable hybrids showed the highest yields over four year period. Other authors also noticed that the highest yielding hybrids have the lowest stabilityand prefer good environments (Delic *et al*., 2009, Stevanovic *et al*., 2011).

Conclusion

Based on four year results it can be concluded that in FAO 300 two hybrids (ZP 366 and ZP 388) outperformed standard commercial hybrid ZP 341, so those can be proposed for further commercialization. Hybrid ZP 366 had higher average yield compared to ZP 341 in all four years of testing, in optimal and also in poor agro ecological conditions. According to these results, ZP 366 can be recommended for growing in both, intensive and extensive conditions. On the other side, hybrid ZP 388 had very high yields in optimal conditions in 2014. and 2016., while in dry seasons 2015 and 2017. it had lower yield than ZP 341 and ZP 366. Thus, this hybrid can be recommended for intensive maize production.In FAO 400 commercial hybrids ZP 427 and ZP 434 were highest yielding and there is a need to include new, promising hybrids in these trials. In FAO 500-600, during 2014-2017some new hybrids were tested, but none of them in all four years of testing. There are several new, recently registered ZP hybrids which will be included in strip trials and compared with commercial ones.

Abstract

Movement of tractors and mobile systems during the plant production can be divided into the movement of the interior of the plot and the movement on the headlands. Both movements result in soil compaction of various intensity, whereby the compaction is more expressed on the headlands, unlike the interior of the plot due to lower speeds in turning. The consequences of compaction create unfavorable conditions for growth and development of cultivated crops, permanent soil damage, reduction of yields and increase production costs. The paper shows the results of measuring the impact of tractors and mobile systems movement on soil compaction changes and the yield of various maize hybrids. The tests were carried out in the conditions of the Jablanica County, and the soil compaction was measured by the Eijkelkamp 6.0 penetrologer in accordance with EN 5140, while the soil moisture was measured by the Theta probe. Cone resistance was measured at the inner part and the edges of the plot at the beginning of the vegetation (emergence phase) and at the end of the vegetation (harvesting phase). The aim was to determine the effects of changes in soil compaction, on the growth, development and yield of various maize hybrids. The obtained results showed that the soil compaction in the emergence phase of maize on the headlands was on average higher by more than 92% in relation to the interior of the plot. In the harvesting phase on the headlands, more intensive soil compaction values were measured in relation to the plot's interior, and the soil compaction increased more than 57%. Due to the more intensive soil compaction on the headlands, the yields of maize on average were reduced more than 60%, compared to the plots interior.

Keywords: *Soil compaction, tractor, maize, yield.*

Introduction

Soil compaction is one of the main forms of degradation and it is present in total degradation with 11%, while in Europe it is the cause of degradation of 33 million hectares of agricultural land (Akker and Cararache, 2001; Lynden, 2000). The threat of soil compaction is greater today than in the past because of the dramatic increase in the size of farm equipment (Sjoerd, 2004). On the headlands compared to inner parts of plots, at all the plants because of slower speeds of machinery and longer exposing to the normal charges, soil compaction is more intensive. On a headland were measured high values of soil compaction, 4.35, or 4.50MPa (Savin *et al.*, 2004; Nikolić *et al.*, 2007).The increase of soil compaction is especially expressed at a depth of up to 50 cm, with more difficult water and nutrients absorption, an increased risk of erosion and increased energy consumption for soil cultivation (Yavuzcan *et al.*, 2005; Šeremešić *et al.*, 2005; Gajić, 2006; Manuwa *et al.*, 2011; Jerzy and Leszek, 2012). The negative consequences of soil compaction are multiple and significantly affect the reduced yield (Ishaq *et al.*, 2001; Friton, 2001; Nikolić *et al.*, 2002 Savin *et al.*, 2003; Hamza and Anderson, 2005; Ramazan *et al.*, 2012). By applying lighter mechanization, soil

compacting can be significantly reduced with reduced energy consumption (Mouazen and Palmqvist, 2009). The soil compaction changes with the depth of measurement, and the cone resistance when measuring soil compaction at a depth of 20-30 cm was 2 MPa (Yavuzcan *et al.*, 2002). In the emergence stage of maize, the soil compaction on the headlands was higher for 102.87% in relation to the interior, and in the harvesting phase for 59.37% (3.30 MPa - 35 cm depth). In the inner part of the plot the yield of maize grains was higher for 42.81 % in relation to the headlands (Jarak *et al.*, 2005).

Material and Methods

During 2017, in the vicinity of Leskovac (43°04'18.7" N 21°46'52.9" E and 43°01'08.0" N 21°56'11.0" E) the influence of the movement of tractors and mobile systems on changes in the soil compaction and the yield of different maize hybrids on two soil types were carried out. In production of maize, the usual production technology was applied, and all the tools were aggregated to the tractor of power 36.9 kW. The tests were carried out on Vertisol and Aluvium soil, and maize hybrids were represented NS 4051, AGR DIAN, ZP 666, AS 534 and Bećar. The soil compaction was measured in the inner part of the plot and on the headlands, in the maize sprouting phase and in the collection phase. In order to make a consideration of the right headlands, the parcels were selected along the path, so that the turning of the tractor and mobile systems was done only on a plot where the proper headland were formed Width of each experimental plots was 20 m, and length of 100 m. A penetrologer was used to measure soil compaction - Eijkelkamp hardware version 6.0, software version 6.03. Soil compaction was measured at the depth of 0-35 cm, by pressing the cone of the surface 1 cm^2 with the tip of the cone 60^0, in accordance with the standard NEN 5140, the penetration rate of 2 cm sec^{-1}, with no deviation greater than 0.5 cm s^{-1}. The used embossing cone was of standard size, and the standard is defined according to ASAE standard (ASAE S313.1). During the measurement, the penetrologer inclination did not exceed 3.5^0 in relation to the vertical (the position was monitored by the penetrologer libel), while the penetration rate was followed by a speed indicator in a display that was close to the median position (position between "S" and "L"). The soil moisture at the moment of compression measurement was determined by the Theta probe and expressed in % vol. On the soil type Vertisol, in the emergence phase of maize, soil moisture in the interior of the plot was on average 27%, and on the slopes 23%, and in the harvesting phase 19% and 17%. On the soil type Aluvium, in the emergence phase, the soil moisture was 26% in the interior of the plot and 23% on the slope, while in the harvesting phase it was 24% in the interior and 20% on the slopes. The cone resistance was measured in 5 repetitions with a distance of 2 m between the measuring points, with the centre point located in the middle of the headland.

Results and Discussion

On Figure 1 and 2 the soil compaction values are shown during the production of different maize hybrids during the emergence phase, during the harvesting phase of maize in the interior of the plot and on the headlands. Based on the results in Figure 1, it is noticed that the soil compaction in the interior of the plot during the maize sprouting phase was significantly lower in relation to the headland, and with the increase in the depth of measurement, the compaction increased. Soil moisture during the measurements in the inner part of the plot amounted to an average of 27%, and on the headlands of 23%. The lowest soil compaction of Vertisol type was measured at the stage of maize sprouting in the interior of the plot at 0-5 cm and it was on average 0.19 MPa, while on the headland at the same depth the compression was 0.37 MPa, which is the increase of soil compaction from 94.74 %. The highest compression in this phase of measurement was measured on the headland at a depth of 35 cm and amounted to 4.46 MPa, while the inner part of the plot composed at the same depth 2.32

MPa, which is a difference of 92.24%. Similar differences in the soil compaction were observed in other measurement depths in the maize emergence phase (Figure 1). In the phase of harvesting the maize with the depth of measurement, soil compaction increases, where the soil is significantly more compact on the headlands than in the inner part of the plot.

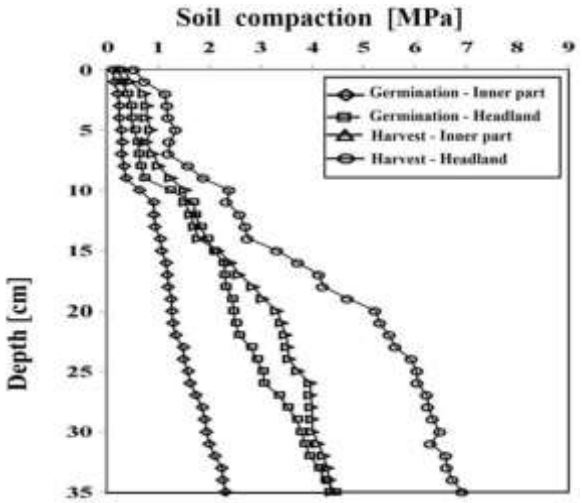

Figure 1. Vertisol's compaction in the inner part of plots and on the edges in the stage of sprouting and harvesting of maize [MPa]

At a depth of 0-5 cm in the interior of the plot, the average soil compaction of 0.65 MPa was measured, while at the same depth on the headland the compression was 1.01 MPa, an increase of 55.38%. On the headlands, the highest values of soil compaction were measured at a depth of 35 cm, and 6.54 MPa, while in the inner part of the plot the compaction was 3.98 MPa, which is a difference of 64.32%.The soil moisture in the maize harvesting phase was 19% in the inner part of the plot, and 17% on the headlands.

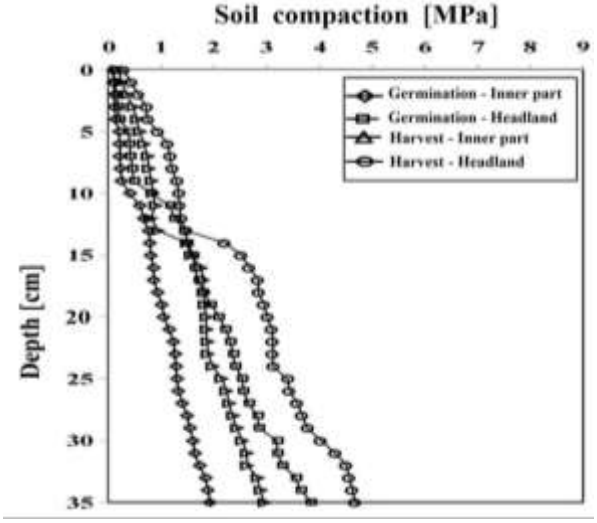

Figure 2. Soil compaction of Alluvium soils in the inner part of the plot and on the headlands in the stage of sprouting and harvesting maize [MPa]

The results of the measurements shown in Figure 2 show that the lowest soil compaction in the Aluvium in maize sprouting phase was in the inner part of the plot at a depth of 0-5 cm, on

average 0.11 MPa, while on the headlands at the same depth the soil compaction amounted to 0.20 MPa. The highest values of soil compaction were measured at a depth of 35 cm 3.84 MPa, while in the inner part of the plot at the same depth the compaction amounted to 1.93 MPa, which makes a difference of 98.96%. Similar differences in the soil compaction were also observed in other depths of measurements in the maize sprouting phase (Figure 2). The average soil moisture in the maize sprouting phase was 26% in the interior of the plot and 23% on headland. At the stage of harvesting the maize, the lowest compaction was measured in the interior of the plot at a depth of 0-5 cm, on average 0.38 MPa, while on the same depth, on the headland, the compaction amounted to an average of 0.55 MPa (Figure 2). On this type of soil, during the maize harvesting phase, the highest soil compaction values were measured at a depth of 35 cm, so the increase in soil compaction on the headlands related to the inner part was 58.82%. Similar differences are observed in other measurement depths. The soil moisture at the stage of harvesting the maize was 24% in the inland plot and 20% on the headland.

Extremely high values of compaction of soil type Vertisol, in the harvesting period, can be explained as a result of unfavourable climatic condition during the measuring, as well as the result of soil properties of this soil type.

The results of our research agree with the findings of other authors (Savin *et al*., 2004; Yavuzcan *et al.,* 2005; Šeremešić *et al.,* 2005; Gajić, 2006; Nikolić *et al.,* 2007; Jerzy and Leszek, 2012; Ramazan *et al.*, 2012; Manuwa *et al.*, 2011).

Due to the intensive soil compaction, the yield on the headland decreased related to the inland of the plot, so that the maize yield on the Vertisol-type soil on the headlands was 3.12 t ha^{-1} to 3.43 t ha^{-1}. In the interior of the plot the yield of maize varied from 5.45 t ha^{-1} to 5.95 t ha^{-1} (hybrid AGR DIAN, or NS 4051). A similar influence of the compaction on the yield was recorded in other maize hybrids (Figure 3).

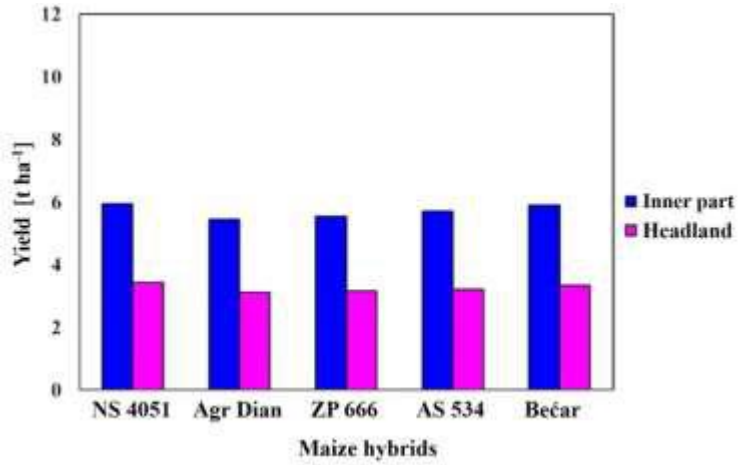

Figure 3. Average values of maize yields realized on Vertisol type

More intensive soil compaction on the headland compared to the inland of the plot showed a significant influence on Aluvium, so that the yields achieved were significantly lower and varied in the range of 5.24 t ha^{-1} to 6.70 t ha^{-1} (hybrid ZP 666). Inside the land plot yields were within the range of 9.18 to 11.90 t ha^{-1} (hybrids NS 4051, ZP 666) (Figure 4). In the case of other maize hybrids, a similar effect of changes in compression on the yields was recorded.

The obtained results show the negative impact of more intensive soil compaction on the headlands compared to the inland of the plot, so that the yields of maize in the examined

conditions on both types of soil on the headland in relation to the inland were lower by more than 60% on average.
Similar results in their research are also reported by other authors (Ishaq *et al.*, 2001; Friton, 2001; Nikolić *et al.*, 2002; Savin *et al.*, 2003; Hamza and Anderson, 2005; Jarak *et al.*, 2005; Ramazan *et al.*, 2012).

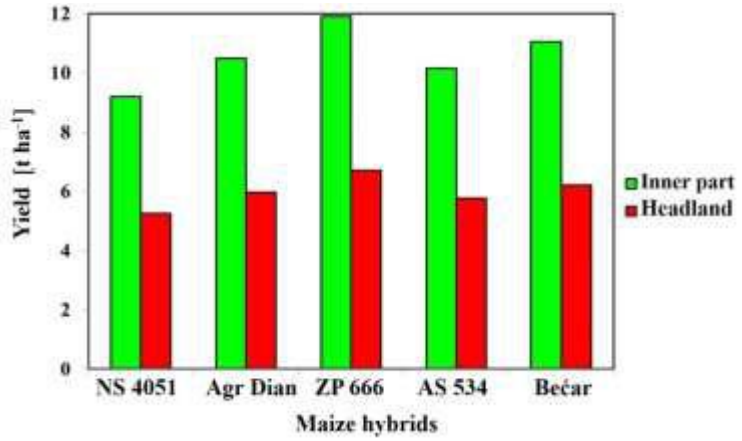

Figure 4. Average values of maize yields realized on Alluvium type

Conclusions

On the basis of the obtained results, it can be concluded that in the inland of the plot, the soil compaction is lower in relation to the headland in both crops, with the lowest values being measured in the phase of emergence on both types of soil. Soil compaction increased in the depth of measurement during all stages of measurement. The lowest compaction in the maize-sprouting phase was measured on the Aluvium at a depth of 0-5 cm and an average of 0.11 MPa, and the highest on Vertisol at a depth of 35 cm on average 4.46 MPa. Soil compaction on the headlands was, on average, higher by over 92% compared to the interior of the plot on both types of soil individually at all depths of measurement. In the harvesting phase, the lowest compaction was measured at Aluvium at a depth of 0-5 cm, it was an average 0.38 MPa, and the highest on Vertisol at 35 cm 6.54 MPa. On the headlands of both soil types at all depths of measurements, compaction was more than 57% higher. The mutual differences in the compactness of both soil types between the plot's interior and the headlands in the maize harvesting phase are less expressed than in the emergence phase, with less generalized compaction values on Aluvium than on Vertisol. As a result of intensive compaction, yields on the headland were reduced related to the inner part of the plot, so the lowest yields were measured on the headlands (Vertisol) 3.12 t ha^{-1} (hybrid AGR DIAN). The highest maize yields were achieved in the interior of the plot (Aluvium) 11.90 t ha^{-1} (hybrid ZP 666). The average reduction in the yield of maize on the headland in relation to the interior of the plot for all the hybrids is over 60%

MICROPROPAGATION OF CHRYSANTHEMUM CULTIVARS IN SERBIA

Slađana JEVREMOVIĆ*, Angelina SUBOTIĆ

Institute for Biological Research "Siniša Stanković", University of Belgrade, Serbia
*Corresponding author: sladja@ibiss.bg.ac.rs

Abstract

Micropropagation represents the plant tissue technique for rapid multiplication of valuable plant material. Last two decades there has been a continuous research effort in Institute for Biological Research "Siniša Stanković" (Belgrade, Serbia) for development of fast and efficient protocol for micropropagation of chrysanthemum cultivars. Recently, the focus of our research is on implementation of developed protocol in practice. The aim of this work was to evaluate potential for mass plant production by classical micropropagation approach of five commercially growing cultivars of chrysanthemums in one growing season from single shoot as a starting plant material. Aseptic stem segment cultures (88 explants/cultivar) were established from all investigated cultivars (12-54%) in January. Shoot multiplication was evaluated during next three subcultures with shoot multiplication index of 2.8-6.1 newly developed shoot/explant depending on cultivar and culture media. The best shoot multiplication was obtained on nutritional medium supplemented with α-naphthalene acetic acid (NAA) and 6-benzylaminopurine (BAP). Regenerated shoots were rooted (100%) in following three weeks on plant growth regulator free medium. About 3500 micropropagated chrysanthemum plantlets were rooted and planted in field in nurseries during May. Plants were successfully (100%) acclimatized *ex vitro* and flowered during autumn. As a final result we evaluated the cost of *in vitro*-derived chrysanthemum plantlets produced by our protocol for micropropagation.

Keywords: *stem segment culture, plant production, in vitro.*

Introduction

Chrysanthemum (*Chrysanthemum morifolium* Ramat.) represents a significant group of cut flowers which belong to the *Asteraceae* family. Besides rose, chrysanthemums are the second economically most important ornamental crop in the world (Teixeira da Silva, 2004). Name chrysanthemum originated from the Greek words for gold flower (lat. *krus anthemon*). Chrysanthemums are also called »autumn roses«, because they were in the past used as cut flower during late summer and whole autumn. Nowadays, because of their ornamental values and many new cultivars, they have grown and have been available on the market during the whole year. Plant tissue culture techniques, especially micropropagation, as a method for rapid production of clonally identical plants, is very useful method for large-scale production of chrysanthemum cultivars. Also, it is essential for breeding of new chrysanthemum cultivars (Teixeira da Silva and Kulus, 2014). Conventionally chrysanthemum cultivars are commonly propagated by root suckers and terminal cuttings. Micropropagation as a method for shoot proliferation from different type of initial explants provides a useful tool for production of genetically uniform plants originated for donor plant. Plant regeneration of chrysanthemum cultivars has been reported, for the first time about fifty years ago (Hill, 1968). There are numerous reports of adventitious shoot regeneration from various explants of chrysanthemum (summarized in Teixeira da Silva, 2004). Investigation of different ways for *in vitro* plant regeneration of more than 30 chrysanthemum cultivars has studied in Institute for Biological Research "Siniša Stanković" Belgrade, Serbia in last more than 20 years of research (Radojević *et al*., (1994, 2000), Jevremović and Radojević (1995, 2004). Successful plant regeneration was achieved in culture of nodal and internodal segments, but also the culture of

leaf tissue (Trifunović *et al*., 2005). Shoots were induced by the adventitious shoot development on initial explants with very short callus phase which implicate high level of true-to-typeness of regenerated plantlets. The clonally fidelity of some cultivars was confirmed even after ten days of multiplication in culture *in vitro*. The flower shape and colour of 'spider' type chrysanthemum cultivars were not changed after long term micropropagation (Jevremović *et al*., 2006, 2012). Also, chrysanthemum cultures can successfully survive cold storage at 4 °C up to six months without subculturing which is very important for planning of plant production during the year (Trifunović et al., 2006).
Main objective of this work is to evaluate the potential for plantlet regeneration from one initial plant shoot/cultivar during one growing season, from January to October. Additional value of this study is the evaluation of the cost of *in vitro* derived chrysanthemum plantlets according to our protocol for plant regeneration.

Material and methods

As a starting plant material we used one single shoot of the donor plants of five different chrysanthemum cultivars collected from the growers from village Vinča near the Belgrade (Table 1). For early flowering cultivar with 'Cremist' flower type we used one shoot for variety with white and one shoot for variety with yellow flowers.

Table 1. List of *Chrysanthemum morifolium* cultivars used in our study.

Cultivar code	Time of flowering	Type	Colour
RH2	Early autumn	'Margaret'	white
RH3	Early autumn	'Cremist'	white, yellow
KH1	Late autumn	'Spider'	yellow
KH2	Late autumn	'Viking'	yellow
KH4	Late autumn	'Daisy'	magenta

Nodal and internodal stem segments were cut in peace (5 cm) and washed for one hour in tap water. After this period of time, for surface sterilization stem segments were replaced to 100 ml glass bottles filled with 30% solution diluted in sterile water of commercial bleach ('Varikina') with 4% NaOCl. After 20 min the solution was drained off and stem segments were washed three times for five min with sterile water. For shoot induction sterilized stem segments were cut transversely on 0.5 cm peace and placed on culture medium for shoot induction. Basal culture media (BM) used in our study were the same for all culture media and composed of Murashige and Skoog mineral solution and vitamins (Murashige and Skoog, 1962) solidified with 7% agar with 3% sucrose and 100 mg/L myo-inositol. Surface sterilized nodal segments were cultured on BM medium for shoot induction which were supplemented with plant growth regulators: α-naphthalene acetic acid (NAA, 0.5 mg/L) and 6 benzylaminopurine (BAP 1.0 mg/L). Shoot multiplication was tested on four culture media supplemented with two auxins indole acetic acid (IAA) and NAA supplemented in two concentrations (0.1 and 0.5 mg/L) and BAP 1.0 mg/L during three successive four weeks long subculture. For shoot rooting, 2 cm long apical shoots were grown on BM medium without plant growth regulators for 3 weeks. Nutritional media were sterilized in an autoclave for 20 min at 114 °C. All cultures were grown with photoperiod 16h day/8h night at 23 ± 2 ° C.
Rooted plantlets were washed of adhering agar under warm water before planting. Rooted plantlets are potted in peat and perlite (3:1) before grown in the field conditions. Survival of initial explants was measured seven days after initiation of culture as number of green aseptic stem segments without any sign of contamination. The shoot multiplication index was measured as a number of *de novo* formed shoots on initial explants regenerated after four

weeks of culture. Shoot multiplication was evaluated in a period of February-May. All data were subjected to statistical analysis using STATGRAPHICS and analysis of variance (ANOVA) using least significance (LSD) tests.

Results and discussion

Micropropagation represents a method for mass production of disease-free and true to type planting material within a short duration and limited space. It is performed under aseptic and controlled environment. Plant regeneration of many chrysanthemum cultivars has reported up to date and an establishment aseptic culture is a first and crucial step for evaluation of successful protocols for micropropagation of different plant species (Teixeira da Silva, 2014). After seven days of culture 12.2-54.0% initial stem segments survived depending on cultivar and were free of contamination (Table 2). The rest of the cultures were lost due to mostly fungi contamination. Relatively high level of contamination is not unexpected since we used donor plants which were grown in the field.

Table 2. Establishment of aseptic cultures of chrysanthemum cultivars.

Cultivar code	EXPLANTS	
	Cultivated	Aseptic (%)
RH2	56	14 (25.0)
RH3	190	32 (16.8)
KH1	74	9 (12.2)
KH2	71	20 (28.2)
KH4	50	27 (54.0)
Total	441	102

Aseptic internodal and nodal chrysanthemum segments (Fig. 1A) were placed on new culture medium and first adventitious shoots were developed within the next four weeks (Fig. 1B). All regenerated shoots were multiplied during three successive subcultures by activation of axillary shoots by nodal segment culture without callus phase (Fig. 3C). *De novo* induced axillary shoos formed 6-11 nodal segments after four week of subculture, which were used for shoot multiplication in next subcultures. We tested the effect of two auxins in two concentrations on shoot multiplication of chrysanthemum cultivars. The best shoot multiplication was achieved on culture media supplemented with NAA as auxin where the highest number of newly developed shoots was recorded in all cultivars (Table 3). Chrysanthemum cultivar with white 'Margaret' type of flowers showed the greatest regeneration potential (6.1 shoot/explant) on medium where the ratio of plant growth regulators (NAA:BAP) was 1:10. For all other cultivars culture medium with 1:5 ratio of plant growth regulators was more appropriate for shoot multiplication.

Table 3. The effect of culture media on shoot multiplication of chrysanthemum cultivars.

Cultivar code	SHOOT MULTIPLICATION			
	IAA		NAA*	
	0.1	0.5	0.1	0.5
RH2	2.7 ± 0.5^{a}	2.9 ± 0.3^{a}	$\underline{6.1 \pm 1.0^{b}}$	2.8 ± 0.5^{a}**
RH3	1.5 ± 0.1^{a}	1.5 ± 0.1^{a}	1.7 ± 0.1^{a}	$\underline{4.0 \pm 0.2^{b}}$
KH1	2.0 ± 0.1^{a}	1.7 ± 0.05^{a}	1.6 ± 0.2^{a}	$\underline{3.2 \pm 0.2^{b}}$
KH2	$2.1 \pm 0.2^{a,b}$	1.4 ± 0.3^{a}	1.5 ± 0.2^{a}	$\underline{3.2 \pm 0.4^{b}}$
KH4	$2.2 \pm 0.3^{a,b}$	1.4 ± 0.1^{a}	1.1 ± 0.1^{a}	$\underline{4.9 \pm 0.4^{b}}$

*Medium was supplemented with 1 mg/L BAP and different concentrations of auxins IAA or NAA. The concentrations of auxins were in mg/L ** Mean ± standard error. Values signed in rows with different letter are significantly different according to LSD test.

The combination of plant growth regulators NAA and BAP are important for shoot growth of many chrysanthemum cultivars (Kaul *et al*., 1990, Teixeira da Silva, 2004). The use of other plant growth regulators, such as urea-type citokinins can improve shoot multiplication of chrysanthemum cultivars, but there can be some side effects like hyperhidricity (Jevremović and Radojević, 2004).

We cultured apical shoots on medium without plant growth regulators at the beginning of May for root initiation (Fig. 1D) and shoots were successively rooted (100%) after three weeks of culture (Fig. 1E). Plantlets height, average number of developed roots varied 7.3-10 root/shoot and the length of regenerated roots varied depending on cultivars (Table 4). *In vitro* produced chrysanthemum shoots can easily rooted on medium without growth regulators and produced plantlets are with good quality (Fig. 1F). This fact is very important in regard of the final cost of *in vitro*-derived plantlets (George and Manuel, 2013).

Table 4. Morphological characteristics of *in vitro*-derived chrysanthemum plantlets.

Cultivar code	SHOOT	ROOT	
	Height (mm)	Nº	Length (mm)
RH2	$62.6 \pm 2.5^{a*}$	9.8 ± 0.5^{c}	58.8 ± 2.7^{c}
RH3	84.6 ± 2.8^{b}	$7.3 \pm 0.3^{a,b}$	37.9 ± 1.2^{b}
KH1	96.8 ± 4.5^{c}	10.0 ± 0.6^{c}	100.5 ± 4.6^{d}
KH2	85.8 ± 4.0^{b}	7.9 ± 0.4^{b}	40.0 ± 3.4^{b}
KH4	114.7 ± 4.7^{d}	6.4 ± 0.3^{a}	32.3 ± 2.8^{a}

* Mean ± standard error. Values signed in columns with different letter are significantly different according to LSD test.

Regenerated plantlets were planted and acclimatized in field conditions (Fig 1 G). In total 173 (RH2), 960 (RH3), 920 (KH1), 360 (KH2 and 1000 (KH4) plantlets were planted at the end of May. In total, from 102 initial explants, 3413 in vitro plantlets were regenerated from the period of five months. All plantlets flowered from September to November depending on cultivar (Fig. 1H).

Figure 1. Micropropagation of selected chrysanthemum cultivars. A Aseptic inernodal stem segments grown 7 days on induction medium. B Indirect shoot induction after 4 weeks of culture. C Shoot culture during multiplication. D Apical shoots before rooting. E Rooted shoot cultures. F *In vitro*-derived plantlets ready for planting. G Plantlets grown in field conditions during August. H Flowered plantlets in late September, cultivar RH3, 'Cremist' flower type.

The true-to-typeness is especially important for ornamental plants. All *in vitro*-derived chrysanthemum plants showed inflorescence colour and shape typical for the cultivars. In our previous study, we find that spider type of chrysanthemum can be very stable during long term micropropagation. Shoots of this cultivar can be propagated more than ten years in culture *in vitro* without any change in flower morphology (Jevremović *et al*. 2012). On the other hand, *in vitro* propagation of some cultivars can be very useful for chrysanthemum breeding as a source of new varieties (Zalewska *at al*., 2007).

Conclusions

We implemented efficient, fast and true-to-typeness protocol for chrysanthemum production by micropropagation in culture *in vitro*. It is possible to regenerate up to 1000 plantlets ready for planting from one donor shoot in a period of five months. The best regeneration potential showed cultivar with yellow spider type of flowers. From initial 9 aseptic stem segments cultured in January more than 920 fully developed plantlets ready for planting were obtained in May. The final cost of chrysanthemum plantlets depended on cultivar. But, if we know that for production of 3413 plants in period of five months from six initial shoots we used 40L of culture media and know that the cost of 1L of culture media is approximately 1 euro, it is not easy to conclude that micropropagation is the method of choice for mass production of chrysanthemum cultivars.

Abstract

From the point of view of agricultural production, alfalfa is one of the most important forage legumes in Serbia and the world. Considering the significant area on which this plant species is grown and production potential of alfalfa, average yields in practice are not high enough. One way to improve the productive performance of alfalfa seed is inoculation of the seed with effective strains of microorganisms, which would allow the better use of potential for the development of plants and microorganisms.In this study the influence of pre-sowing inoculation with individual and combined cultures of rhizobia (*Sinorhizobium meliloti*), azotobacter (*Azotobacter chroococcum*) and actinomycetes (*Streptomyces sp*.) on the weight of alfalfa plants was examined. Analyses were carried out in the beginning of blooming stage. In the experiment the influence of seven variants of microbial inoculation on plant weight was examined on two alfalfa cultivars. After inoculation seed from each inoculum variant were planted in the pots filled with soil. For tested parameter, interaction between cultivar and inoculation resulted in positive effect. Only the application with combined cultures *A. chroococcum* and *Streptomyces* sp.(6) in the variety K-28 did not result in a statistically significant increase in green mass per plant compared to the control.

Key words: *alfalfa, inoculation, cultivar, weight.*

Introduction

Alfalfa is one of the most widely cultivated forage legumes because of its high nutritional quality for livestock, high biomass production and broad adaptability to a wide range of ecological conditions (Herrmann *et al.,* 2010; Bouton, 2012). Its importance as a forage crop lies in its high protein, vitamin and mineral contents, as well as its nitrogen-fixing performance through *Sinorhizobium meliloti* symbiosis (Barnes *et al.,* 1988). The potential for nitrogen fixation via symbiosis is supposed to be, in average, 450 kg ha^{-1} $year^{-1}$ (Fishbeck *et al.,* 1987). Symbiotic nitrogen fixation is a renewable source of nitrogen and an environmentally friendly way of supplying the alfalfa plant and soil with nitrogen (Delić *et al.,* 2016). The bacteria enzyme system supplies a constant source of reduce nitrogen to the host plant and the plant furnishes nutrients and energy for the activities of the bacteria (Shetta *et al.,* 2011). Rhizobia synthesize polysaccharides, vitamins B group, indole-3-acetic acid and cytokine, siderophore production, effect on phosphorus availability, antagonistic activity of rhizobia against plant pathogenic micro-organisms (Denison and Kiers 2004; Baset Mia and Shamsuddin, 2010).

Azotobacter is free-living soil microbe which fixes nitrogen from the atmosphere, aerobic, oval or spherical bacteria that form thick-walled cysts, and may produce large quantities of capsular slime. The beneficial effects of azotobacter are not only due to its ability to fix atmospheric nitrogen, but also to secrete biologically active substances: auxin, gibberellins, pyridoxine, biotin and nicotinic acid (Dobbelaere *et al.,* 2003; Hayat *et al.,* 2010), produces antifungal compounds, antibiotics (Dey *et al.,* 2017). Actinomycetes enhance plant growth producing biologically active substances such as indole-3-acetic acid (IAA) to help growth of roots or produce siderophores to improve nutrient uptake (Suzuki *et al.,* 2000).

These microorganisms are present, in higher or lesser abundance, in the soil and after harvest they can end up on the seed and plant roots. But application of selected microorganisms for seed inoculation leads to better results in crop production. The effect of inoculation depends on host plant activity, species, strain and cell concentration of microorganisms in the inoculum, the structure of indigenous populations, soil type, nutrient pool and toxic metal concentrations, soil health, microbial diversity, and soil disturbances caused by management practices. (Walker *et al*. 2003; de Souza *et al.*, 2015). The use of efficient inoculants can be considered an important strategy for sustainable management and for reducing environmental problems by decreasing the use of chemical fertilizers (Alves *et al.*, 2004).
The aim of this study was to examine the influence of rhizobium, actinomycetes and azotobacter (especially and in combinations) on the green mass of alfalfa.

Material and Methods

The experiment was carried out in 10 l volume vegetation pots in semi-controlled conditions at the Institute for Forage Crops in Kruševac. The soil chemical characteristics were the following: pH/KCl 5.90; pH/H_2O 6.44; total nitrogen 0.138%; humus 2.62%; P_2O_5 6.6 mg 100 g^{-1}; K_2O 24.05 mg 100 g^{-1}.
The experiment was a two-factorial, random block design with 5 replicates, where the first factor was alfalfa cultivar and the second was the variant of microbial inoculation. Research was conducted on two alfalfa cultivars: K-28 (bred in the Institute for forage crops in Kruševac) and Syntéza 1 (bred in Plant Production Research Center (PPRC) in Piešťany.

The inoculation was done using the following inocula:
1. *Sinorhizobium meliloti* ($10.8x10^{11}$ per ml);
2. *Azotobacter chroococcum* ($28x10^{11}$ per ml);
3. *Streptomyces* sp. (actinomycetes), ($7.6x10^{10}$ per ml);
4. *Sinorhizobium meliloti* + *Azotobacter chroococcum*;
5. *Sinorhizobium meliloti* + *Streptomyces* sp.;
6. *Sinorhizobium meliloti* + *Streptomyces* sp.;
7. *Sinorhizobium meliloti* + *Azotobacter chroococcum* + *Streptomyces* sp.;
8. Control – no inoculation.

The *Sinorhizobium meliloti* cultures were grown on YM substrate by Vincent (1970), *A. chroococcum* cultures were grown on the liquid substrate by Feodorov (1949), and *Streptomyces* sp. were grown on the substrate by Krasiljnikov (1965). These microorganisms were obtained from the collections of the Department of Microbiology of the Faculty of Agriculture in Novi Sad. Alfalfa seed was sterilized with 0.2% solution of $HgCl_2$ and 70% ethanol, rinsed several times with sterile tap water and then immersed in the corresponding inocula. Ten seeds from each inoculum variant were planted in pots filled with soil. In each pot, 10 ml of the appropriate inoculum was added.
Green mass per plant (g).was measured in first cut at the beginning of flowering.
The results were processed using the statistical package STATISTICA 8.0. The significance of the difference between the investigated treatments was determined by analysis of variance, and LSD tests.

Results and Discussion

The results obtained showed that the application of microorganisms and combinations thereof can affect on the green mass of alfalfa. For the successful alfalfa cultivation, the microbial inoculants are more and more applied for the better utilization of potential for the development of plant and microorganisms N fixation efficiency (Delić *et al.*, 2007). The

application of microbial inoculants may reduce the use of expensive nitrogen fertilizers, speeds up the decomposition of pesticides and increases the biological activity of soil (Djukić et al., 2006).

The plants of both examined cultivars of alfalfa in treatments with inoculation had significantly greater weight than the control in almost all variants (Table 1). Only the application with combined cultures A. *chroococcum* and *Streptomyces* sp.(6) in the variety K-28 did not result in a statistically significant increase in green mass per plant compared to the control.

Table 1. The effect of inoculation and cultivar on the green mass per plant (g)

Cultivar	Variants	Green mass per plant (g)
K-28	1	4,87 ^{j}
	2	5,02 ^{i}
	3	4,72 ^{k}
	4	4,09 ^{n}
	5	4,60 ^{l}
	6	4,05 $^{n, o}$
	7	5,31 ^{h}
	8	4,00 ^{o}
Syntéza 1	1	6,58 ^{b}
	2	6,78 ^{a}
	3	5,51 ^{g}
	4	6,08 ^{d}
	5	5,63 ^{f}
	6	6,00 ^{e}
	7	6,25 ^{c}
	8	4,37 ^{m}

Note: Mean values with the same superscript(s) are not significantly different according to Fisher's LSD test ($p < 0.05$)

.

By using mixed inoculum of combined cultures microorganisms - *Sinorhizobium meliloti*, *Azotobacter chroococcum* and *Streptomyces* sp., Jarak *et al*. (2007) achieved the fastest germination and maximum height and weight of alfalfa. Similar results were reported by Andjelković *et al.* (2014) in the research of the effect inoculation of these microorganisms in the production of alfalfa in acid soil. In our research better results were determined in treatments inoculated with individual cultures of microorganisms or a combination of all three species of bacteria than using combination of two cultures microorganisms.

In comparison with the control, the best effect on the green mass of alfalfa was recorded with monovalent inoculum *Azotobacter chroococcum* in cultivar Syntéza 1 (Table 1). Numerous investigations into the influence of inoculation on crops have proved its positive effects (Biswas *et al*., 1994; Kizikaya, 2008; Stamenov *et al*., 2012). The plants of cultivar of alfalfa Syntéza 1 had a bigger green mass in the variants of inoculation, and control in comparison to cultivar K-28. The effect of inoculation on the plant can be direct, that is through plant growth promotion, or indirect, that is through improving plant nutrition via the better development of the roots, and it is difficult to distinguish between them (Nihorimbere *et al*., 2011).

Conclusions

The results obtained in our research indicate that the plant response to the application of appropriate microorganisms and their combination was generally positive. Microorganisms used for the inoculation of alfalfa seeds can, also, be found in the soil, though their number may vary. However, the indigenous strains were not always effective, so the inoculation with selected microorganism strains should be used for the better results in the alfalfa production.

Abstract

Meadow fescue (*Festuca pratensis* Huds.) is one of the important perennial fodder grasses for animal feed production on grasslands and pastures, with high yield potential and biomass quality. As in other species, basic requirement for successful breeding of meadow fescue is variability of the initial material in breeding programme. The collection examined consisted of five populations and six meadow fescue cultivars. The study was conducted in an experimental field of the Institute for Forage Crops, on degraded alluvium soil type. The trial was set up in a space plant nursery with plant to plant distance 60x60cm as a randomized block design with 30 plants per genotype in two years. The aim of these study was to determine and compare variability of the most important phenological (heading date) and morphological traits (plant height, sward diameter, length, width and leaf number, terminal internodes length and the number of tillers per plant), seed yield components, herbage quality, green mass and dry matter yield of populations and cultivars. The data were analysed by ANOVA. Populations have demonstrated higher variability compared to cultivars for most studied parameters. The highest genetic coefficient of variability in populations was determined for seed yield per plant and number of tillers per plant (CV_G 66.05% and 63.35% in second year of investigation). In cultivars, the highest genetic coefficient of variability determined for green mass yield and number of tillers per plant (CV_G 50.47% and 46.65% in second year). The lowest variability in both studied groups in both investigated year, was determined for heading date. Broad sense heritability (h_b^2) was high, in both studied groups, in populations and cultivars, for all investigated traits. The highest heritability was determined for plant height (99.32%) and ash content (99.84%) in populations, and for green mass yield in the third cut (99.67%) in cultivars.

Keywords: *meadow fescue, variability, heritability, populations, cultivars*.

Introduction

Meadow fescue is forage grass species well adapted to continental climates where it is an alternative to *Lolium perenne.* Meadow fescue is diploid (2n = 14), with high level of self-incompatibility. It is a species of increasing importance, particularly in the northern hemisphere, where it dominates in the meadows and pastures (Casler and Santen, 2000). It has been usually used for intensive production of hay meadows. These species is highly productive, with high nutritive value (Babić et al., 2012). The herbage quality changes depending on the stage of maturity, but because it flowers late compared with other forage grasess, high quality of herbage is retained for a long time. This is a very important characteristic for meadow fescue to be a component in grass-legumes mixtures. Meadow fescue is very compatible with many forage species, especially legumes like alfalfa, red and white clover and sainfoin. Of grasses, associates with *Phleum pratense* is in use in temporary cutting grassland in north areas, like Scandinavia. It is one of the most productive forage perennial grasses, especially in extreme environmental conditions, like summer drought or winter hardiness. By quality and digestibility, meadow fescue can be compared to species of

the genus *Lolium* (Kölliker, 1998). Also, meadow fescue is very tolerant to grazing; therefore pastures where it dominates are long lasting. It can be grown as a pure crop, but more often in mixtures with other grasses and legumes.

First step in grass breeding process is the determination of genetic variability of breeding material. The existence of genetic variability within available breeding material (autochthonous populations, breeding populations and cultivars) influences the choice of breeding material and ensures success of a plant breeding program. Autochthonous populations have natural variation and very often have satisfactory yielding performance in comparison with cultivars (Babić et al., 2014), and often can be used for direct phenotypic selection and for cultivars release (Posselt and Willner, 2007). Most of created cultivars contain autochthonous populations and represent great and important resource of genetic variability. Variability within populations and cultivars of meadow fescue were documented for important agronomical traits, forage yield, and forage quality (Kanapeckas et al., 2005; Babić, 2009).

The genetic variability of all traits important for breeding process represents a basic prerequisite for successful selection. The primary aim in meadow fescue forage breeding is obtaining cultivars with a high yield and improved quality for livestock feed. The aim of this investigation was to determine genetic variability of five breeding populations and six cultivars. The most important breeding criteria in meadow fescue breeding programs, like as other forage grasses, are increasing of forage yield and digestibility, disease resistance and drought (Sokolović et al., 2012) and frost tolerance and persistency (Sokolović et al., 2010). Since is meadow fescue use as a component of grass-legume mixtures in Serbia, dry matter yield and quality, persistency and rust resistance is most important breeding criteria of this species.

Material and methods

Investigated collection consisting of five breeding populations and six cultivars of meadow fescue was investigated during a two years period. Breeding populations have passed 2 cycles of selection. Four of them originated from the local populations, collected mainly in Eastern Serbia (OP-1, OP-2, OP-3 and OP-4), and the population OP-5 originated from Czech Republic. Cultivars included in this study were: Kruševački 21 (K-21) (Serbia), Jabeljska (Slovenia), Premil, Pradel, Preval (Switzerland) and Rožnovska (Czech Republic). The study was conducted in an experimental field of the Institute for Forage Crops, on degraded alluvium soil type. The trial was set up in a space plant nursery with plant to plant distance 60x60cm as a randomized block design with 30 plants per accession in three replications.

Variability of heading date (HD) and morphological traits (plant height (PH), sward diameter (SD), leaf length (LL), leaf width (LW), number of leaves per tiller (NLT), first internodes length (FIL), number of tillers per plant (NTP)), seed yield components (panicle length (PL), lower panicle branches length (LPBL), number of branches in panicle (NBP), seed yield per plant (SYP), 1000 seed weight (1000 SW), green matter yield (GMY) and dry matter yield per plant (DMY) were investigated in 2 years. Biomass quality (crude protein (CP), crude fibre (CF), crude fat (CF), BEM and ash) was determined by the Weende system, in the first cut. All data were analysed by mono-factorial analysis of variance for both years of research, due to large differences in agroecological conditions in studied years, which reflected largely on the achieved results.

Genetic (σ_g^2) and phenothypic (σ_f^2) component of variance were calculated according to the formulas:

$$\sigma_g^2 = \frac{MS_2 - MS_3}{r} \qquad \sigma_f^2 = \sigma_g^2 + \sigma_e^2$$

Broad sense heritability (h_b^2) was calculated for all traits according to the formula:

$$h_b{}^2 = \frac{\delta_g{}^2}{\delta_f{}^2} \cdot 100$$

Coefficients of genetic (CV_G) and phenotypic variation (CV_F) were calculated in the following manner:

$$CV_G = \frac{\sqrt{\sigma_g^2}}{\overline{X}} \times 100 \qquad CV_F = \frac{\sqrt{\sigma_f^2}}{\overline{X}} \times 100$$

Results and discussion

For successful breeding and creation of new cultivar of meadow fescue, as well as other species, one of the basic conditions is existence of variability in the starting breeding material. For successful breeding is necessary to know the structure of genetic and phenotypic variance and heritability of most important and functionally related traits.

Calculated values of genetic and phenotypic components of variance, heritability and coefficients of genetic and phenotypic variation of meadow fescue populations and cultivars are shown in Table 1 and 2.

HD - heading date, PH - plant height, SD - sward diameter, LL - leaf length, LW - leaf width, NLT - number of leaves per tiller, FIL - first internodes length, NTP - number of tillers per plant, PL - panicle length, LPBL - lower panicle branches length, NBP - number of branches in panicle, SYP - seed yield per plant, 1000 SW - 1000 seed weight, GMY - green matter yield, DMY - dry matter yield per plant, CP - crude protein, CF - crude fibre, CF - crude fat

Relationship of genetic and phenotypic variance for all pheno-morphological traits, GMY, DMY and quality traits (except BEM) indicate that the variability of these traits in this collection of breeding populations and cultivars largely derived from plant genotype. For these traits broad sense heritability was high, which means that these traits largely depend on genetic factors. The high heritability values determined for these traits, indicates the great proportion of genetic to total phenotypic variability of the traits and suitability for breeding.
For seed components traits and BEM ratio of genetic and phenotypic variance was significantly different, indicating the significant influence of ecological factors on variability of these traits in these collection. For these traits broad sense heritability was lowest. Based on the results can be concluded that these traits are quite variable, so significant variation in some individual genotypes can be expected depending on environmental factors and the year of investigation.

P – Populations, C – Cultivars
HD - heading date, PH - plant height, SD - sward diameter, LL - leaf length, LW - leaf width, NLT - number of leaves per tiller, FIL - first internodes length, NTP - number of tillers per plant, PL - panicle length, LPBL - lower panicle branches length, NBP - number of branches in panicle, SYP - seed yield per plant, 1000 SW - 1000 seed weight, GMY - green matter yield, DMY - dry matter yield per plant

Genetic and phenotypic coefficients of variation are relative indicators of variability. They are used to compare the level of variability of traits expressed different units of measure. The most variable traits, as expected, are number of tillers per plant, green and dry matter yield per plant and seed yield per plant, in both year of investigation (Table 1 and 2). The lowest genetic and phenotypic coefficients of variation in both year determined for heading date in breeding populations and cultivars also. Similar results presented Kanapeckas et al., 2005. and Babić, 2009. Fang et al., 2004. reported that heading date and plant height had very low

genetic coefficient of variation, while the seed production traits like plant seed yield, seed weight per panicle and panicle fertility exhibiting the highest genetic coefficient of variation values. As expected, for most studied traits calculated higher values for genetic and phenotypic coefficients of variation in breeding population than in cultivars.

Conclusion

In two-year study of genetic variability of pheno-morphological traits, seed yield components and biomass quality five breeding populations and six cultivars of meadow fescue high genetic variability were determined. The relationship of genetic and phenotypic variance, broad sense heritability and coefficients of variation for the most important traits, especially for number of tillers per plant, green and dry matter yield, leaf length and seed yield per plant indicate a high breeding potential of investigated breeding populations and cultivars in meadow fescue breeding process. High values of broad sense heritability for most traits indicate that an improvement of these traits could be possible and predictable in these collections. The influence of genotype on all traits was highly significant. Share of genetic to phenotypic variance for all pheno-morphological traits, GMY, DMY and quality traits (except BEM), indicating that the variability of these traits is largely derived from plant genotype and consequently the heritability of these traits was high.

For most studied traits parameters of variability were similar for breeding populations and cultivars included in investigation except genetic and phenotypic coefficients of variation who are calculated highly values in breeding population than in cultivars.

Abstract

The objective of this experiment was to identify and quantify individual invert sugars (glucose, fructose, sucrose) organic acids (citric acid, malic acid), total anthocyanins, anthocyanin glycosides (delphinidin 3-glucoside, delphinidin 3-rutinoside, cyanidin 3-glucoside, cyanidin 3-rutinoside), vitamins (C, A, B3) and minerals (K, Ca; Mg, Na, P, Cu, Zn, Fe) in berry and leaf extracts of black currant. The extracts prepared from black currant leaves and berries exhibited different characteristics. Berries had higher contents of the tested parameters compared to leaves. Fructose was the dominant invert sugar in all extracts, followed by glucose, while the amount of sucrose was very low. Berry extracts contained 4.35 times more fructose than leaf extracts, and glucose was 3.92 times higher in berries than in leaves. The main organic acid was citric acid, whereas twice as low quantities of malic acid were observed in all tested berries and leaves. The content of total anthocyanins ranged from 289.2 to 12.3 mg C3G 100 g^{-1} in berry and leaf extracts, respectively. In the present research, cyanidin-3-rutinoside was the most abundant anthocyanin in both berries and leaves. The major vitamin in the tested black currant was vitamin C (213.5 and 38.7 mg 100 g^{-1}, respectively), whereas the most abundant mineral was K (328.1 and 20.3 mg 100 g^{-1}, respectively). The results suggested that black currant berries and leaves can be used as valuable ingredients for functional foods.

Keywords*: black currant, berry, leaf, chemical properties*

Introduction

Black currant (*Ribes nigrum* L.) has been recognized as a good source of polyphenols, especially anthocyanins, phenolic acid derivatives, flavonols and proanthocyanidins, compared to other berries (*e.g.*, strawberries and raspberries) (Karjalainen *et al*., 2009; Mattila *et al*., 2011). The fruit of black currants is a rich source of sugars and organic acids as important primary metabolites. The contents of sugars and acids and the sugar/acid ratio are important compositional parameters influencing the sensory properties and consumer acceptance of berry products (Sandell *et al*., 2009; Laaksonen *et al*., 2012). Analyses of black currant constituents have revealed that the fruit has high levels of vitamins and minerals, especially potassium, calcium, magnesium, and iron (Hegedűs *et al*., 2008; Lefevre *et al*., 2011). Vitamins and minerals are very important in biological processes as they promote normal growth and development, and play a vital role in preventing some chronic diseases (Gorinstein *et al*., 2001). Also, leaves of black currants are an excellent source of total phenols, flavonoids and phenolic acids (Tabart *et al*., 2006; Raudsepp *et al*., 2010). Recent papers on epidemiological studies have summarized the positive contribution of black currant berries and leaves to human health, including their antimutagenic, antimicrobial, anti-inflammatory, anti-cancer and antihypertensive properties (Declume, 1989; Puupponen-Pimiä *et al*., 2005; Mazza, 2007; Tabart *et al*., 2012).

Considering that there are not many scientific studies on the chemical compounds present in berries and leaves of black currant, the objective of this research was to identify and quantify chemical properties in berry and leaf extracts of black currant.

Material and Methods

Aerial parts of black currant (*Ribes nigrum* L.) were collected in Čačak, Western Serbia, during 2012-2014. To obtain comparable samples, berries were sampled at full ripeness in June, while leaf samples were collected in July, at the stage of full development. Berries and leaves were taken from the inner and outer ranges of the bush.

The chemical analysis of the berries and leaves included the following parameters: 1. Invert sugar components (glucose, fructose, sucrose) in berry samples, as determined by high-performance liquid chromatography (HPLC; Waters Breeze, Milford, USA), with absorbance measured in the range of 210 to 327 nm. 2. Organic acids (citric acid, malic acid), as analyzed using a Hewlett-Packard HP1100 system equipped with a photo diode array detector (Palo, Alto, CA, USA), with absorbance measured in the range of 490 nm to 600 nm. 3. Total anthocyanins, as assessed by the single pH and pH differential method, with absorbance measured at $\lambda = 515$ nm and $\lambda = 700$ nm. 4. Anthocyanin glycosides (delphinidin-3-glucoside, delphinidin-3-rutinoside, cyanidin-3-glucoside and cyanidin-3-rutinoside), as determined using a Perkin Elmer Series 400 high performance liquid chromatograph equipped with a Hewlett-Packard 1040A photodiode array detector, with absorbance measured at 290, 350 and 520 nm. 5. Vitamin C, as assessed by a Perkin Elmer UV/VIS spectrometer (Lombda 25), with absorbance measured at 665 nm. 6. Vitamins A and B3, as determined by a high-performance liquid chromatograph (HPLC; Milford, MA, USA) fitted with a fluorescence detector, with absorption spectra recorded at 347 nm for vitamin B3 and 295-330 nm for vitamin A. 7. Mineral content of the fruit, as determined by flame atomic absorption spectrometry using a Varian Spectar AA 200 instrument equipped with a GTA 110 graphite furnace (Varian, USA). Phosphorus concentration was assessed by spectrophotometry - Spectrophotometer MA9523-SPEKOL 211 (ISKRA, Horjul, Slovenia), at 725 nm, using the molybdenum blue phosphorus complex.

The results are presented as mean ± standard deviations of three determinations. Statistical analyses were performed using Student's t-test and one way analysis of variance. Multiple comparisons of means were made by LSD (least significant difference) test. A probability value of 0.05 was considered significant. All computations were made by employing the statistical software (SPSS, version 11.0).

Results and Discussion

Glucose, fructose and sucrose are the major sugars, citric acid is a major organic acid, and malic acid is present in minor concentrations in the fruit of black currant (Hummer and Barney, 2002; Rubinskiene *et al*., 2006; Milivojević *et al*., 2009). Individual invert sugars and organic acids in berry and leaf extracts were identified by the HPLC-DAD analysis, with the corresponding results presented in Figures 1 and 2. The results show significant differences between berries and leaves. Berries had a higher content of invert sugars and organic acids compared to leaves. Fructose was the dominant invert sugar in all extracts, followed by glucose, while the amount of sucrose was very low. Berry extracts (127.1 mg g^{-1}) contained 4.35 times more fructose than leaf extracts (29.2mg g^{-1}), and glucose (83.2mg g^{-1}) was 3.92 times higher in berries than in leaves (21.2 mg g^{-1}). The amount of sucrose was very low in both extracts. In this study, the main organic acid was citric acid, while twice as low quantities of malic acid were observed in all tested berries and leaves. The content of citric acid in berry extracts was 56.1 times higher than that in leaf extract. Heiberg *et al.* (1992) reported that the sugar content in black currant berries was 9.0%, of which fructose made up 45%, glucose 40% and sucrose 15%. The ratio of sugars to organic acids is an important indicator of perceived taste, maturity/ripeness and general quality, which may serve as an index of consumer acceptance (Bordonaba and Terry, 2008). Fruits with pleasant sensory characteristics are often considered to have a high content of sugars and a relatively low amount of acids (Zheng *et al*., 2009).

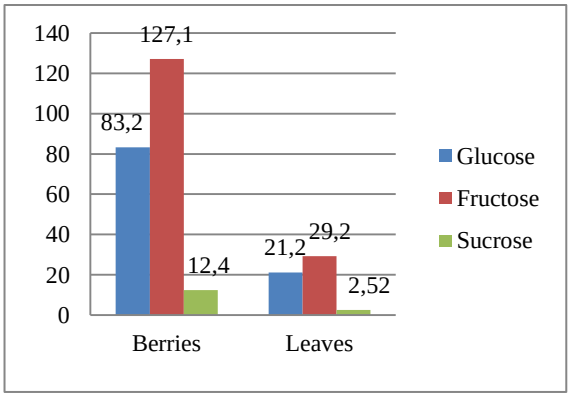

Fig. 1. Invert sugars in berry and leaf extracts

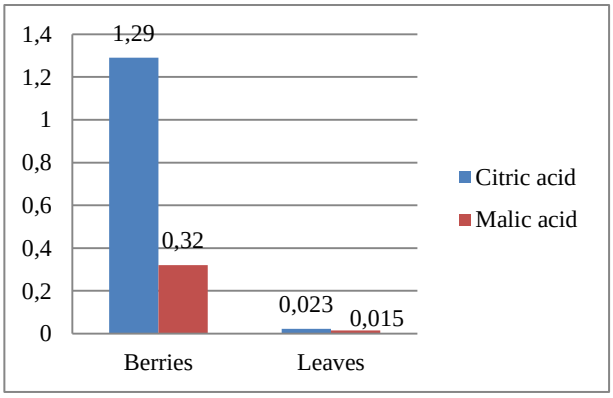

Fig. 2. Organic acids in berry and leaf extracts

Black currant berries are an important source of anthocyanins with concentrations up to four-fold greater than that of other common fruits. Anthocyanins are the major group of phenolics in black currants, accounting for approximately 80% of total phenolics. The four main pigments delphinidin 3-O-glucoside, delphinidin 3-O rutinoside, cyanidin-3-O-glucoside and cyanidin-3-O-rutinoside contribute up to 97% of total anthocyanins in black currants (Anttonen and Karjalainen, 2006). Many studies have reported high concentrations of phenolic compounds in black currant berries and, to a lesser extent, in buds and leaves (Maatta *et al*., 2003; Tabart *et al*., 2006; Raudsepp *et al*., 2010). Total anthocyanins and anthocyanin glycosides in berry and leaf extracts are presented in Table 1.

Table 1. - Total anthocyanins and anthocyanin glycosides in berry and leaf extracts of black currant

	Total anthocyanins mg C3G 100 g^{-1}	Cyanidin -3-rutinoside mg 100 g^{-1}	Cyanidin -3-glucoside mg 100 g^{-1}	Delphinidin -3-rutinoside mg 100 g^{-1}	Delphinidin -3-glucoside mg 100 g^{-1}
Berries	289.2±4.50	44.7±0.38	21.6±0.27	2.61±0.11	3.74±0.11
Leaves	2.07±0.29	1.23±0.02	1.15±0.01	0.06±0.0001	0.16±0.003

The levels of total anthocyanins in berry extracts (289.2 mg C3G 100 g^{-1}) were higher than in leaf extracts (12.3 mg C3G 100g^{-1}). Berries had 23.5 times more anthocyanins than leaves. Compared with the present results, Tabart *et al*. (2011) and Vagiri *et al*. (2013) recorded a higher content of total anthocyanins, while Moyer *et al*. (2002) and Lister *et al*. (2002) reported similar contents. Delphinidin-3-rutinoside was the most dominant anthocyanin in studies by Wu *et al*. (2004) and Szajdek and Borowska (2008), whereas cyanidin-3-rutinoside predominated elsewhere (Rubinskiene *et al*., 2006; Oszmianski and Wojdylo, 2009). In the present research, cyanidin-3-rutinoside was the most abundant anthocyanin in both berries and leaves. Black currants are a major source of vitamins, which in turn provide black currants with powerful antioxidant effects (Walker *et al*., 2010; Raudsepp *et al*., 2010; Nour *et al*., 2011).

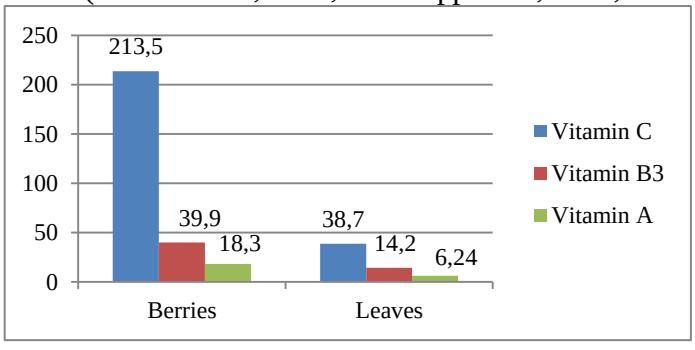

Fig. 3. Vitamins in berry and leaf extracts

In comparison with other fruits, black currants are low in calories, and they have significant levels of vitamin A, vitamin B1, vitamin B3, vitamin E, iron, potassium and calcium (Hummer and Barney 2002). Ascorbic acid and anthocyanins are the most beneficial compounds contributing to the antioxidant capacity of the black currant fruit (Lister *et al*., 2002). The results on the contents of vitamins in black currant berries and leaves are given in Figure 3. Berry extracts were found to have higher contents of vitamins in comparison to leaf extracts. The major vitamins in the tested black currant berries and leaves were vitamin C (213.5 and 38.7 mg 100 g^{-1}, respectively), followed by vitamin B3 (39.9 and 14.2 mg 100 g^{-1}, respectively) and vitamin A (18.3 and 6.24 mg 100 g^{-1}, respectively). Zurawicz *et al*. (2000), Siksnianas *et al*. (2006) and Nes *et al.* (2012) reported a higher content of vitamin C in berries than the value reported in the present study. Tabart *et al*. (2006) found a higher content of vitamin C in the berry than in the leaf. Moyer *et al*. (2002) emphasized that the significant antioxidant capacity of black currant fruits and their processed products is accounted for by a very high content of vitamin C. High levels of vitamin C and polyphenols contribute to the antioxidant, anti-inflammatory, antimicrobial and anticarcinogenic activities of the fruit (Mazza, 2007). Black currants are rich in minerals which contribute to their health benefits. Borges *et al*. (2010) and Lugasi *et al*. (2011) reported that currant fruits are a good source of minerals and natural antioxidant substances. In the present experiment, eight essential minerals were determined, and the results are given in Table 2. High levels of macro and microminerals were present in the berries compared to leaves.

Table 2. - Mineral contents in berry and leaf extracts of black currant

	K mg 100 g^{-1}	Na mg 100 g^{-1}	Ca mg 100 g^{-1}	Mg mg 100 g^{-1}	P mg 100 g^{-1}	Cu mg 100 g^{-1}	Zn mg 100 g^{-1}	Fe mg 100 g^{-1}
Berries	328.1±0.84	25.4±0.27	30.9±0.21	24.2±0.31	188.9±0.26	0.46±0.007	0.30±0.003	5.47±0.11
Leaves	20.3±0.02	0.14±0.003	2.56±0.01	0.67±0.02	23.6±0.07	0.012±0.0001	0.028±0.0001	0.52±0.006

Mineral levels in berry extracts were higher by 8.00 (P) to 181.4 (Na) times than in leaf extracts. The main elements in berry and leaf extracts included K, P, Ca, Mg and Na, whereas Fe, Cu and Zn were present in minor amounts. The most abundant mineral was K, with levels of 328.1 and 20.3 mg 100 g^{-1} in berry and leaf extracts, respectively, whereas Zn had the lowest levels (0.30 and 0.028 mg 100 g^{-1}, respectively). The macro- and microelements followed the order: K > P >Ca> Mg > Na > Fe > Cu > Zn. Compared to the present experiment, Perkins-Veazie and Collins (2001), Hummer and Barney (2002) and Cosmulescu *et al*. (2015) reported higher values for K and Ca, but significantly lower levels for P, Fe and Na, whereas Nour *et al*. (2011) obtained comparable levels of Ca and Zn, a higher content of Mg, and lower amounts of K, Na and Fe. Lefevre *et al*. (2011) determined high levels of minerals, especially P, Ca, Mg, and Fe, in the fruits, whereas Tahvonen *et al*. (1993) obtained significant amounts of Ca, Mg, Fe, Mn and Zn. As found by Hegedűs *et al*. (2008), black currants, which offer dietary benefits and produce numerous physiological effects in humans, have high levels of macroelements (Ca, K, Na, Mg and P), but relatively low concentrations of microelements (Fe, Cu and Zn).

Conclusions

Berry and leaf extracts of black currant are exceptionally rich sources of sugars, acids, anthocyanins, vitamins and minerals, and they provide an interesting nutritional alternative. Berries had higher contents of the tested parameters compared to leaves. Generally, the results on chemical properties indicated that berries and leaves can be used in primary agricultural production, as well as in the pharmaceutical and food industries.

Abstract

The experiment was established in the experimental field at the experimental field of Secondary Agricultural-chemical school "Dr Djordje Radic" in Kraljevo (Serbia) during the 2009/10 and 2010/11 growing seasons. The objective of this study was to investigate the influence of genotype and environment on the yield of winter barley cultivars (Rekord, Grand, NS 565 and Atlas). The following characteristics were analysed: grain yield, 1000 grain weight and test weight. The grain yield of the studied genotypes of winter barley ranged from 4.340 t/ha (2009/10) to 5.217 t/ha (2010/01), while the average grain yield was 4.779 t/ha. The highest two-year average of 1000 grain weight (50.22 g) were obtained by NS 565 cultivar. The largest two-year average value of test weight was found in the cultivar Rekord (69.25 kg/hl). The average value of all genotypes was 66.78 kg/hl. Highly significant influence of the year on grain yields and 1000 grain weight were established at investigated winter barley cultivars by variance analysis, while genotype influence on 1000-grain weight and test weight was significant. Significant differences in 1000-grain weight at investigated barley cultivars were found relative to the interaction of environmental factors and cultivars. In view of the ever-changing climate change and the global warming trend, barley production is becoming increasingly risky and unstable. In such circumstances, there is a need for the creation of varieties, which in addition to good agronomic qualities, will be characterized by high and stable yields.

Key words: *cultivar, grain yield, winter barley*

Introduction

Barley cultivars that were in production until the end of the eighties were characterized by the lower yields, good technological quality and higher stem sensitive on lodging. Barley is globally cultivated on an area of about 47.5 million hectares, an average yield of 2.6 t/ha being realized making it the fifth grown crops (maize, rice, wheat and soybeans). In Serbia, barley is grown on 84.166 ha with an average yield of 2.9 t/ha and ranks third with 244.081 tons (FAO, 2010). The largest areas under barley are in Russia, Australia, Ukraine and Canada **(**FAO, 2010).

The interaction between the genotype and environment greatly limits the effectiveness of selection, if it is performed only on the basis of the average yield. Varieties that have a smaller contribution to interaction are less sensitive to changing environmental conditions, such varieties are stable (Bratković et al., 2014; Đekić et al., 2012; Jelić et al., 2014). New varieties are characterized by good technological quality, better resistance to lodging and diseases, shorter stem and more efficient assimilates usage (Pržulj et al., 2004).

The need for a variety of short or long growing season depends on the environmental conditions of a particular area. In winter barley often variations in yield can be detected, also between the years and between locations (Đekić et al., 2011; 2015; Popović et al., 2011). The 1000 grain weight and test weight are direct components of grain yield and change under the

influence of environmental factors, but primarily varietal characteristics. They indicate the grain size and are important criterions in breeding barley.
The aim of this study was the determination of the cultivars and ecological environmental factors influence on differences in stability and adaptability of cultivars regard the grain yield, 1000 grains weight and test weight of tested winter barley cultivars, as well as specificity cultivars exploring regard growing seasons conditions.

Materials and methods

Experimental design and statistical analysis

During the 2009/10 and 2010/11 growing seasons, three cultivars of winter barley (Rekord, Grand, NS 565 and Atlas), cultivated at the experimental field of Secondary Agricultural-chemical school "Dr Djordje Radic" in Kraljevo (Serbia) were investigated. The studied soil is extremely acid pseudogley. Experiments have been conducted in randomized block systems, with a plot size of 50 m^2 (10 m x 5 m) in five replicates. The usual techniques for barley production were applied, and it was done in the optimum sowing time in late October. Fertilizers have used in the 300 kg/ha of form of complex NPK fertilizer (8:24:16, superphosphate (17% P_2O_5) and ammonium nitrate (AN) 34.4% N). The following properties were analyzed: grain yield (t/ha), 1000 grain weight (g) and test weight (kg/hl).
On the basis of achieved research results the usual variational statistical indicators were calculated: average values, standard error and standard deviation. Statistical analysis was made in the module Analyst Program SAS/STAT (SAS Institute, 2000).

Meteorological conditions

Kraljevo area is characterized by a moderate continental climate, which general feature is the uneven distribution of rainfall by months. Data in Table 1 for the investigated period (2009-2011) clearly indicate that the years in which the researches were conducted differed from the typical multi-year average for Kraljevo region, regarding the meteorological conditions. The average air temperature in 2009/10 was higher by 0.9°C and 2010/11 was higher by 0.4°C than the average of many years.

Table 1. Middle monthly air temperature and precipitation amount (Kraljevo)

Interval	Months									Average
	X	XI	XII	I	II	III	IV	V	VI	
Mean monthly air temperature (°C)										
2009/10	11.3	8.2	3.8	1.1	2.7	7.2	12.1	16.6	20.2	9.2
2010/11	9.2	11.1	2.7	0.3	0.6	6.6	12.2	15.6	20.4	8.7
Average	11.5	6.2	1.4	-0.5	2.3	6.5	11.7	16.2	19.1	8.3
Monthly sums of precipitation (mm)										Sums
2009/10	137.9	63.1	97.7	34.4	81.6	38.6	100.2	84.0	136.4	773.9
2010/11	93.6	34.1	64.9	28.1	59.2	48.9	37.1	82.9	71.7	520.5
Sums	53.1	55.7	54.8	44.0	42.8	44.7	65.1	74.9	86.5	521.6

The sum of rainfall precipitation in 2009/10 was higher by 226.4 mm, where the sum of rainfall in 2010/11 was 27.0 mm lower than the average of many years and with a very uneven distribution of precipitation per months. During the April in 2009/10 it was 100.2 mm of rainfall, what was 46.2 mm more compared with the perennial average. During the June in 2009/10 it was 136.4 mm of rainfall, what was 52.8 mm more compared with the perennial average. Regard the high importance of sufficient rainfall amounts during the spring months, particularly May for small grains production, the distribution and amount of rainfall over the growing season 2010/11 were considerably more favorable, what resulted with the increment of yields during that year. Based on the fact that sufficient amounts of rainfall in

these months are very important for the successful production of cereal crops it can be concluded that the years in which the researches were conducted were favorable for the barley growing.

Soil conditions

Agrochemical properties of the treated pseudogley are very unfavorable. Soil analyzes have been performed by standard chemical methods, as follows: pH in H_2O and KCl, electrometrically with a glass electrode in a 1:2.5 suspension; content humus by Kotzmann's method; total nitrogen has been determined by the Kjeldahl's method, available phosphorus and potassium by Egner-Riehm's Al method. The humus content in the surface layer of soil was low (2.18), and a substitution and total hydrolytic acidity were quite high (pH H_2O=5.24, KCl=4.48). The examined soil is characterized by very unfavorable composition of the adsorptive complex. The soil was medium provided with total nitrogen (0.14% N), while the available phosphorus content was low (under 7-8 mg/100 g of soil P_2O_5). When it comes to the content of easily available potassium the treated soil is well supplied, and it belongs to an average supplied soil class (13.8 mg/100 g of soil K_2O).

Results and discussion

Average values of yield (t/ha), test weight (kg/hl) and 1000 grain weight (g) at investigated winter barley cultivars grown at the experimental field of Secondary Agricultural-chemical school "Dr Djordje Radic" in Kraljevo (Serbia) during two growing seasons, 2009/10 and 2010/11, are presented in Table 2.

Table 2. Average values of investigated barley cultivars characteristics

Traits	Cultivar	2009/10			2010/11			Average		
		x	S	Sx	x	S	Sx	x	S	Sx

The grain yield of winter barley significantly varied across years, from 4.340 t/ha in 2009/10 to 5.217 t/ha in 2010/11 (Table 2). During the first year of investigations, cultivar NS 565 achieved the highest grains yield (4.646 t/ha), followed by Grand (4.384 t/ha), while the lowest yield was at Atlas cultivar (4.093 t/ha). During the second year of investigations (2010/11), the yield of NS 565 cultivar was the highest with 5.670 t/ha. Average grains yield observed in the two-year period was the highest at NS 565 and Grand varietes (5.158 t/ha and 4.786 t/ha), while the lowest yield was obtained by Atlas cultivar (4.492 t/ha). Spring month April in 2009/10 were the surplus of precipitation, what affected unfavorable on the crops. Larger precipitation amounts during the spring months the growing season 2009/10 (March-May) caused rising groundwater levels and

flooding of agricultural land. The excessive amount of moisture influenced the poorer heading and filling of grain, lodging of crops, the abundance of the weeds and the intense occurrence of the disease in the examined triticale and other winter grains. Regard the high importance of sufficient rainfall amounts during the spring months, particularly May for small grains production, the distribution and amount of rainfall over the growing season 2010/11 were considerably more favorable, what resulted with the increment of yields during that year. Considerable variation in yield depending on years of research have established Bratković et al. (2014), Đekić et al. (2011), Jelić et al. (2014), Madić et al. (2009) and Popović et al. (2011).

During the first and second years of investigation, NS 565 cultivar achieved the highest average 1000 grain weight (46.24 g and 54.21 g) compared with other tested barley cultivars. Average 1000 grain weight observed in the two-year period was the highest at NS 565 variety (50.22 g), while the lowest was obtained by Atlas cultivar (39.47 g). The 1000 grain weight of winter barley significantly varied across years, from 41.96 g in 2009/10 to 49.36 g in 2010/11 (Table 2). Malting barley is expected to have 1000 grain weight of 40 and 46 g and test weight of 68 to 75 kg/hl (Paunović et al., 2006).

The test weight of winter barley significantly varied across years, from 67.56 kg/hl in 2009/10 to 66.00 kg/hl in 2010/11 (Table 2). Average test weight observed in the two-year period was the highest at Rekord variety (69.25 kg/hl), while the lowest was obtained by Grand cultivar (62.84 kg/hl). Generally, the test weight of barleys ranged from 52 to 72 kg/hl (Pržulj et al., 2004).

**Statisticaly significant difference (P<0.05)* ***Statisticaly high significant difference (P<0.01)*

Table 3 shows the impact of the year, cultivar and interaction of year x cultivar on yield, 1000-grain weight and test weight. Analysis of variance was found highly significant effect of year on the yield (F_{exp}=26.627**) and 1000-grain weight (F_{exp}=29.506**). Analysis of variance in barley cultivars tested showed statistically highly significant differences in 1000-grain weight (F_{exp}=11.508**) and test weight (F_{exp}=29.506**) in relation to the growing season (P<0.01). Statistically significant difference in 1000-grain weight is determined under the influence of the interaction year x cultivar. Grain quality is a qualitative property influenced by the genetic factors and environmental factors, as well as their interaction, so the variety can behave in some years as beer or fodder/forage crop, which can be determined by the testing and

directed for a particular purpose (Pržulj et al., 2004; Paunovic et al. 2006; Madić et al. 2009; Popović et al. 2011; Bratković et al., 2014; Đekić et al., 2015).

Table 4. Correlation coefficients by studied environments in barley

Correlations between the traits analyzed in the 2009/10			
	Grain yield (t/ha)	1000-grain weight (g)	Test weight (kg/hl)
Grain yield (t/ha)	1.00	0.36^{ns}	-0.02^{ns}
1000-grain weight (g)		1.00	0.39^{ns}
Test weight (kg/hl)			1.00
Correlations between the traits analyzed in the 2010/11			
Grain yield (t/ha)	1.00	0.40^{ns}	0.18^{ns}
1000-grain weight (g)		1.00	0.30^{ns}
Test weight (kg/hl)			1.00

Correlation coefficients by studied environments in barley in the two growing season, are shown in Table 4. Positive and non significant correlations were found between the grain yield and 1000-grain weight in all growing season. Barley yield in 2009/10 was negatively correlated with test weight (Table 4). Negative correlations of yield and 1000-grain weight, seeds that are not significant, are confirmed in their study of barley by Dodig (2000).

Conclusion

Based on the gain results during the two-year investigation on four winter barley cultivars, it can be concluded that the grain yield of barley ranged from 4.492 t/ha (Atlas) to 5.158 t/ha (NS 565). More favourable conditions in 2010/11 resulted in a higher average the grain yield value (5.217 t/ha) compared to 2009/10 (4.340 t/ha). The average 1000-grain weight in the study was 45.66 g, with a variation of 41.96 g in the vegetation year 2009/10 to 49.36 g in the vegetation year 2010/11. During the 2010/11, statistically significantly higher grain yield per area unit, as well as 1000 grain weight was achieved, compared with 2009/10 year.

Abstract

The study was carried out in a stationary field trial involving fertilization over a two (2010/11 and 2011/12) growing seasons, three varieties of winter triticale were investigated (Favorit, Trijumf and KG Tempo) at the Small Grains Research Centre in Kragujevac (in central Serbia). The following properties were analyzed: grain yield (t/ha), 1000 kernel weight (g), test weight (kg/hl) and chemical quality of grain. The grain yield of triticale significantly varied across years, from 3.773 t/ha in 2010/11 to 4.815 t/ha in 2011/12. The highest two-year average of grain yield (4.499 t/ha) and 1000-kernel weight (49.80 g) were obtained by KG Tempo cultivar. The highest two-year average of test weight (71.23 kg/hl) were obtained by Trijumf variety. The highest two-year average value of protein content was found in the variety Favorit (11.170%). Highly significant influence of the year on grain yield, 1000-kernel weight, test weight and protein content was established for investigated winter triticale cultivars by variance analysis. Triticale yield in 2010/11 and 2011/12 years was positively correlated with test weight and 1000-grain weight, but negatively correlated with protein content. Environmental conditions have had a significant effect on grain yield and quality in triticale. Grain yield shows a tendency to increase in the years having a higher total amount and better distribution of rainfall during critical plant development stages.

Keywords: *grain yield, protein, test weight, triticale*

Introduction

Triticale is cereal species gained by cross-breeding of wheat and rye. The yield per unit area is the result of the action of factors of variety fertility in interaction with environmental factors. Therefore, the yield is relative term and is determined by the variety, environmental conditions and the level of applied technology. Yield is largely dependent on the genetic potential, which could be defined as yield of variety which was grown in conditions on which it had adapted, with adequate amounts of water and nutrients and efficient control of pests, diseases, weeds and other stresses (Đekić et al., 2014; Milovanovic et al., 1998). Yields vary considerably primarily as a result of agro-ecological conditions during the growing season (Biberdžić et al., 2012; Đekić et al., 2010; Đurić et al., 2016; Janušauskaitė, 2013; Kendal et al., 2014; Kondić et al., 2012; Milovanović et al., 2012).

Triticale presented high tolerance regard the acid soils, as well as good productive results on sandy soils (Đekić et al., 2010; 2014). Soil acidity frequently affects agricultural production in Serbia. Triticale was planting where corn did not prosper, as well in the areas with moderate climate (Djekic et al., 2011). It could be said that it inherited very good up to excellent tolerance regard the most important pathogens and small grains pests. Triticale presented high adaptability on local agro-ecological conditions, and it was influenced on stabile yield reaching.

New perspective triticale lines and varieties has more and better filled grain, higher yield, grain mass and farinaceous content, while proteins and lysine was smaller compared with older varieties (Kendal et al., 2014; Milovanović et al., 2014).
The aim of this study was the determination of the cultivars and ecological environmental factors influence on differences in stability and adaptability of cultivars regard the grain yield, 1000 grains weight, test weight and protein content of tested winter triticale cultivars.

Materials and methods

Materials and field trials

The study was carried out in a stationary field trial involving fertilization over a two years. During the 2010/11 and 2011/12 growing seasons, three varieties of winter triticale were investigated (Favorit, Trijumf and KG Tempo) at the Small Grains Research Centre in Kragujevac (in central Serbia). The experiments were conducted in randomized block systems, with a plot size of 50 m^2 (5 m x 10 m) in five replications. The sowing was carried out using a machine with row spacing of 12.5 cm. The soil on which the trial was conducted was uniform and well prepared. The amount of seed per square meter amounted to 400-450 viable seeds, depending on the characteristics of varieties. It was sown in the third decade of October, with 400 kg/ha of fertilizer NPK 15:15:15, which was added in the fall, while during the spring fertilization soil was supplemented with 300 kg/ha (KAN 27%N).
The following properties were analyzed: grain yield (t/ha), 1000 kernel weight (g), test weight (kg/hl) and chemical quality of grain. Grain yields were measured for each plot and converted to yield tons per hectare on the basis of 14% grain moisture. The total protein content in the grain was determined by infrared spectroscopy technique on the apparatus Perten DA 7000 (NIR/VIS Spectro-photometer) employing non-destructive method.

Meteorological and soil conditions

This study was conducted over a two growin seasons in the Šumadija region, Central Serbia, on a Vertisol soil, at Kragujevac location, 173-220 m a. s. l. (44° 22′ N, 20° 56′ E), in a temperate continental climate having an average annual temperature of 11.5°C, typical of Šumadija districts in Serbia and a rainfall amount of about 550 mm. Kragujevac area is characterized by a moderate continental climate, which in general is characterized by uneven distribution of rainfall by month.

Table 1. Middle monthly air temperature and precipitation amount (Kragujevac)

	Months									
Interval	X	XI	XII	I	II	III	IV	V	VI	Average
	Mean monthly air temperature (^oC)									
2010/11	10.2	11.4	2.4	0.9	0.5	7.2	12.0	15.8	20.9	9.0
2011/12	10.4	3.1	4.6	0.7	-3.7	8.1	12.9	16.1	23.0	8.4
Average	12.5	6.9	1.9	0.5	2.4	7.1	11.6	16.9	20.0	10.5
The amount of precipitation (mm)										
2010/11	86.9	27.9	50.1	29.1	48.5	20.4	20.8	65.8	32.3	381.8
2011/12	33.3	1.3	43.3	117.2	60.1	5.7	74.5	87.3	57.8	480.5
Average	45.4	48.9	56.6	58.2	46.6	32.4	51.9	57.6	70.4	468.0

The data presented in Table 1 for the analyzed triticale growing season (2010-2012) clearly suggest differences in weather conditions between the years of the study and the long-term mean for the region. The average air temperatures were by 1.5^{o}C and 2.1^{o}C lower in 2010/11 and 2011/12, respectively, as compared to the long-term mean, whereas the sums of rainfall were by 12.5 mm higher in 2011/12 years and lower by 86.2 in 2010/11 years as compared to the long-term mean. Compared to the long-term mean, total rainfall values, especially in the

first year, second and third year, were considerably higher in February, April and May, whereas total rainfall in April 2010/11 decreased by 31.1 mm. Given the high importance of sufficient rainfall amount during the spring months, particularly April and May, for triticale production, the distribution and amount of rainfall over the growing season 2010/11 were considerably more favorable, resulting in increased yields in this year. Apart from the rainfall deficiency during the spring months and the non-uniform distribution of rainfall across months, an increase in average air temperatures was also observed.

The trial at the Small Grains Research Centre in Kragujevac (in central Serbia), was performed on soil that is characterized as smonitsa in process of degradation. The physical properties of the soil are very unfavorable and it belongs to the type of heavy clays. According to the analysis, this is a soil of medium acidity, poor in humus (2.65%), with a substitution and total hydrolytic acidity that were quite high (pH in H_2O=5.99, in KCl=4.91). The soil was moderately provided with total nitrogen (0.14% of N), it is poor in easily accessible phosphorus (P_2O_5=<12 mg/100 g of soil), a medium level of easily accessible potassium (K_2O=14-23 mg/100 g of soil) was recorded.

Statistical Analysis

On the basis of achieved research results the usual variational statistical indicators were calculated: average values. Experimental data were analyzed by descriptive and analytical statistics using the statistics module Analyst Program SAS/STAT (SAS Institute, 2000) for Windows. All evaluations of significance were made on the basis of the ANOVA test at 5% and 1% significance levels.

Results and discussion

Average values of grain yield, 1000 kernel weight, test weight and protein content at investigated Kragujevac's winter triticale varieties are presented in the Table 2.

The grain yield of triticale significantly varied across years, from 3.773 t/ha in 2010/11 to 4.815 t/ha in 2011/12. During the first year (2010/11), the grain yield of the variety KG Tempo was the highest with 4.125 t/ha, while the slightly lower yield was realized by the varieties Trijumf (3.676 t/ha) and Favorit (3.518 t/ha). During the second growing season is better (2011/12), the variety Trujumf achieved the highest yield of grain (5.042 t/ha), while the lowest yield was obtained by the varieties Favorit and KG Tempo (4.529 t/ha and 4.873 t/ha). Achieved statistically significantly higher yields in 2011/12 were, primarily, the result of heavy rainfalls and their good distribution as well as favorable air temperatures during the vegetation period (Table 1). Đekić et al. (2016), states that the air temperatures and the rainfall amount and distribution during the triticale growing season have the greatest impact on high yields and grain quality. Milovanovic et al. (2001), states that in the domestic production conditions, higher yields are achieved by varieties with shorter growing season because they manage to form the largest part of the yield before the advent of high temperatures.

The thousand kernel weight of winter triticale grain was variable, depending on environmental conditions. The second investigation year was significantly more favorable so that the average thousand kernel weight were higher (51.17 g) compared to the first year (46.24 g). Average thousand kernel weight observed in the two-years period were higher at KG Tempo variety (49.80 g), compared by Favorit and Trijumf cultivars (48.90 g and 47.41 g). Previously, many researchers have reported that the thousand kernel weight values of triticale genotypes have ranged from 23.9 g to 54.9 g (Kendal et al., 2014; Janušauskaitė, 2013; Đekić et al., 2014; Madić et al., 2018).

Table 2. Average values of investigated triticale varieties characteristics

Table 2 presents average values for grain test weight across years and varieties. The average values for test weight in all cultivars were as follows: 72.78 kg/hl in 2011/12 and 69.04 kg/hl in 2010/11, suggesting significant variations in test weight during the two years of the study. Average test weight observed in the two-years period was the highest at Trijumf variety (71.23 kg/hl), while the lowest yield was obtained by Favorit and KG Tempo cultivars (70.60 kg/hl and 70.90 kg/hl). Generally, the test weight of triticale ranged from 63 to 80 kg/hl (Barnett et al., 2006; Đekić et al., 2014; Janušauskaitė, 2013; Kendal et al., 2014).

The average crude protein content of triticale significantly varied across years, from 10.120% in 2011/12 to 11.711% in 2010/11 (Table 2). During the all years of investigation (2010/11 and 2011/12), the variety Favorit achieved the highest average protein content (12.120% and 10.221%) compared with other tested triticale varieties. Kendal et al. (2014) have recorded 13.3% up to 14.7% and Perišić et al. (2008), have recorded 14.6% of crude proteins in winter triticale. Djekic et al. (2011), in different winter triticale genotypes, have recorded values ranging from 11.23 to 13.87% of proteins.

Analysis of variance between observed traits of triticale

The analysis of yield variance, 1000-kernel weight, test weight and proteins content of tested winter triticale varieties grown at investigated Kragujevac's during two growing seasons 2010/11 and 2011/12, are shown in Table 3.

Based on the analysis of variance, it can be concluded that there are highly significant differences in grain yield in regard to the year of investigation (F_{exp}=22,1087**), while among the investigated triticale varieties the differences were not significant. Analysis of variance was found highly significant effect of year on the 1000-kernel weight (F_{exp}=108.5666**), test weight (F_{exp}=50.8244**) and protein content (F_{exp}=44.1446**).

Table 3. Analysis of variance of the tested parameters (ANOVA)

Effect of year on the traits analyzed				
Traits	Mean sqr Effect	Mean sqr Error	F (1, 28)	p-level
Grain yield (t/ha)	8.1370	0.368045	22.1087**	0.000063
1000-kernel weight (g)	182.0403	1.676762	108.5666**	0.000000
Test weight (kg/hl)	104.9070	2.064107	50.8244**	0.000000
Protein content (%)	18.9767	0.429875	44.1446**	0.000000
Effect of cultivar on the traits analyzed				
Traits	Mean sqr Effect	Mean sqr Error	F (2, 27)	p-level
Grain yield (t/ha)	0.59682	0.638837	0.934231	0.405221
1000-kernel weight (g)	14.57033	7.401815	1.968481	0.159207
Test weight (kg/hl)	0.99300	5.952445	0.166822	0.847216
Protein content (%)	0.59457	1.104593	0.538274	0.589890
Effect of the year x cultivar interaction				
Traits	Mean sqr Effect	Mean sqr Error	F (2, 24)	p-level
Grain yield (t/ha)	0.240172	0.359636	0.667820	0.522098
1000-kernel weight (g)	2.858333	0.503833	5.673172**	0.009603
Test weight (kg/hl)	7.725000	1.681625	4.593771*	0.020457
Protein content (%)	0.234173	0.432458	0.541493	0.588822

Based on the analysis of variance, it can be concluded that there are not significant differences in grain yield, 1000-kernel weight, test weight and protein content at investigated triticale varieties were found relative to the cultivar of investigation (Table 3). The interaction of the investigated factors (Y x G) exhibits are not statistically significant affect in grain yield and protein content ($p>0.05$), but statistically significant affect in 1000-kernel weight and test weight. The present results confirm the opinion of many authors that the traits analyzed are genetically determined but are strongly modified by the environment and weather conditions (Đekić et al., 2014, 2016; Jelić et al., 2013).

Table 4. Correlations between the traits analyzed

Correlations between the traits analyzed in 2010/2011				
Traits	Grain yield	1000-grain weight	Test weight	Protein content
Grain yield (t/ha)	1.00	0.05	0.17	-0.03
1000-grain weight (g)		1.00	-0.48*	0.09
Test weight (kg/hl)			1.00	-0.03
Protein content (%)				1.00
Correlations between the traits analyzed in 2011/2012				
Grain yield (t/ha)	1.00	0.12	0.23	-0.06
1000-grain weight (g)		1.00	0.06	-0.11
Test weight (kg/hl)			1.00	0.14
Protein content (%)				1.00

Correlations between the analysed traits

The correlations of yield, 1000-kernel weight, test weight and proteins content of tested winter triticale varieties grown at investigated Kragujevac's during two growing seasons 2010/11 and 2011/12, are shown in Table 4. Triticale yield in 2010/11 and 2011/12 years was positively correlated with test weight and 1000-grain weight, but negatively correlated with protein content. Nagatively but significantly correlated with 1000-grain weight and test weight (-0.48*) as shown in Table 4.

Conclusion

The highest yield of grain, weight of 1000 grains and test weight in all triticale varieties were in the vegetation period with moderate temperatures at the time of grain filling and large amount of precipitation in the first vegetation period. Grain yields in triticale cultivars ranged from 4.024 t/ha (Favorit) to 4.499 t/ha (KG Tempo). The average 1000 kernel weight in the study was 48.70 g, with a variation of 46.24 g in the vegetation year 2010/11 to 51.17 g in the vegetation year 2011/12.

Based on the results of the research it can be concluded that a greater number of traits have a decisive role in the formation of grain yield. The contribution of each individual trait may be different in various genotypes and in various environmental conditions so that the correlation between two quantitative traits is not fixed.

Abstract

The possibilities of using algae biomass are numerous, from production bioactive compounds for medical and pharmaceutical industries to their use in agriculture as a biopesticides, biostimulants and biofertilizers. Algal cell growth is significantly affected by light, temperature, aeration, medium and carbon source but also habitat area. The aim of this research was to investigate the effects of different light conditions on algal growth stimulation. Natural day/night (D/N) cycle and continuous artificial lighting (CAL) below 950 lux were tested. Microalgal strains were isolated from two acid soils in Vojvodina, dystric cambisol (pH 4.31) and vertisol (pH 5.50) using BG11 medium. Six selected monoalgal cultures of the genus *Chlorella* (strains C63, C71 and C72), *Dictyosphaerium* (strains D36 and D37), and *Tribonema* (strain T50) were chosen for testing. The growth curve was observed for 24 days. Determination of growth kinetics was monitored spectrophotometrically by measuring the optical density (OD) on the spectrophotometer (Unicam SP600 Series 2, Cambridge England) on 750 nm. The results showed that there was no significant difference in terms of growth rate. Algal strain T50 showed significantly better growing dynamics under CAL relative to D/N cycle. On the other side, under CAL, two *Chlorella* strains (C63 and C71) showed faster initial growth and entered the exponential phase sooner, compared to other examined strains. Faster initial growth indicated better physiological adaptation of the cell metabolism to growth in induction (lag) phase. Grown in their natural environment, photoautotrophic microorganisms showed stable increase in the levels of enzymes and metabolites involved in cell division and carbon fixation.

Keywords: *Terrestrial microalgae, light conditions, spectrophotometry, optical density.*

Introduction

Microalgae biopesticides have a lot of advantages in comparison to the chemical ones. Biologically active products containing beneficial microorganisms can improve soil fertility as well as control plant diseases. Technology for the commercial production of microalgae is economically feasible but there are a lot of potential risks throughout the production process. In order to use microalgae in an industrial process, it must comply to some basic characteristics: a) it must be able to grow in a simple and cheap medium, mineral if possible, preferably with growth factors only (vitamins, nucleotides, micro-elements and acids), b) microalgae should be able to grow rapidly in the medium. c) the products should not include toxic or undesirable materials, especially if they are destined for human consumption and should be suitable for product harvest at the end of the fermentation, and d) with physiological requirements that protect them against contaminants. Different algaes require certain environmental factors for growth. Changes in growth conditions (light and temperature) or nutrient media characteristics can impact on quantity and quality of cells (Liu et al., 2008). The environmental factors affect photosynthesis and growth rate of the algae, cell size, biochemical composition and nutrient requirements. Due to their wide range of potential uses, there is a need to conduct a controlled study in order to establish positive conditions for efficient growth of algal biomass. Direct measurement methods of algal cells are problematic for small volume systems and it is time consuming. Optical density is one of

the simplest methods of measuring cell growth. Optical density at 750nm (OD_{750}) is widely used to monitor algal growth, being inexpensive and reliable (Chioccioli et al., 2014). The energy for photosynthesis is delivered in the form of light. Photosynthesis is a process of sunlight energy conversion in which inorganic compounds and light energy are converted to organic matter by photoautotrophs. Photosynthetic microalgae are directly or indirectly dependent on light as a source of energy necessary for their growth (Masojidek et al., 2013). The most common artificial light sources used in microalgae biotechnology are fluorescent and white-LED with average luminous efficacy of 50-100 and 25-64 lm·W-1, respectively (Blanken et al., 2013). In this experiment the effect of light was evaluated, as one of the main environmental factor, on the growth of microalgae in small scale cultivation system under controled laboratory conditions.

Material and Methods

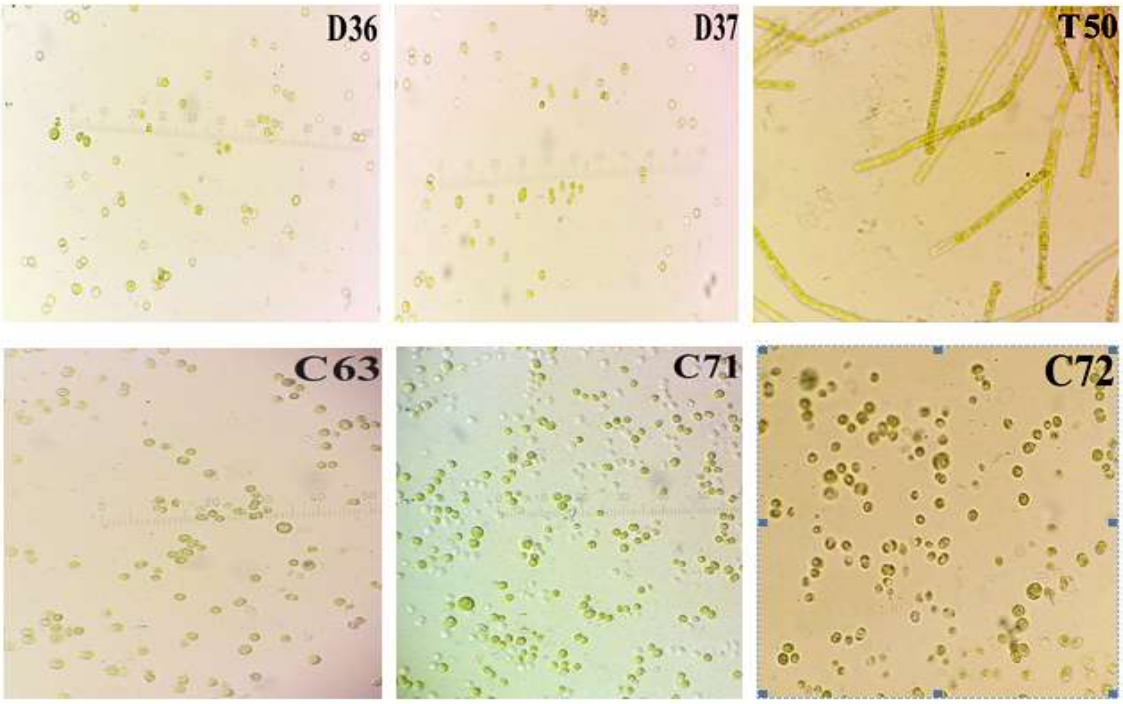
The microalgae species were isolated from acidic arable soils in Vojvodina, Serbia, dystric cambisol (pH 4.31) and vertisol (pH 5.50) using BG11 medium. BG11 medium per one liter of the distilled water contains: 1.5 g $NaNO_3$, 0.04 g K_2HPO_4, 0.075 g $MgSO_4 \cdot 7H_2O$, 0.036 g $CaCl_2 \cdot 2H_2O$, 0.006 g Citric acid, 0.006 g Ferric ammonium citrate, 0.001 g EDTA, 0.02 g Na_2CO_3 and 1ml Trace metal solution A5. The composition of the trace metal mix solution is: 2.86 g H_3BO_3, 1.86 g $MnCl_2 \cdot 4H_2O$, 0.22 g $ZnSO_4 \cdot 7H_2O$, 0.39 g $Na_2MoO_4 \cdot 2H_2O$, 0.08 g $CuSO_4 \cdot 5H_2O$, 0.05 g $Co(NO_3)_2 \cdot 6H_2O$. The pH of BG11 medium was adjusted to 7.1 and autoclaved at 121ºC. To demonstrate the effect of light on algal growth two different light regimes were chosen, natural day/night (D/N) cycle and continuous artificial illumination (CAL) of 950 lm. BG11 medium ($150cm^3$) were inoculated with six selected monoalgal cultures (1 ml). Three microalgae species are from the genus *Chlorella* (strains C63, C71 and C72), two of the genus *Dictyosphaerium* (strains D36 and D37), and strain T50 of the genus *Tribonema*. Taxonomic identification was performed on the basis of morphology and cell size. The experiment was carried out at room temperature (about 24 ºC). Growth curve was observed for 24 days, daily for ten days and later every third day to the end of the experiment. Determination of growth kinetics was monitored spectrophotometrically by measuring the optical density (OD) on the spectrophotometer (Unicam SP600 Series 2, Cambridge England) on 750 nm which is above chlorophyll absorption and outside photosynthetically active radiation (PAR).

Results and Discussion

Microalga *Dictyosphaerium sp.* (Picture 1, D36 and D37) was identified as promising microorganism for biotechnological production of exopolysaccharides (Kumar et al., 2017). Thallus colonial or singlecelled, planktonic, adult cells oval or broadly ellipsoid to spherical, 2–8 μm. The genus *Dictyosphaerium* formerly consisted of 16 species (Comas, 1996; Bock et al., 2011).

Tribonema species (Picture 1, T50) are reported from all over the world in all kinds of freshwater, marine and terrestrial habitats (e.g. Europe, North America, South America, Japan, India, Africa (Lokhorst, 2003), but also in Serbia. Cell wall shape varies from cylindrical with indistinct H-shaped segments (more usual in the smaller species) to slightly inflated with distinct H-shaped segments more apparent in the bigger *Tribonema* species.

Chlorella is a small green microalga (Picture 1, C63, C71 and C72). Cell size is 2-10 μm in diameter and has a high content of about 51-58% protein, 12-17% carbohydrates and 14-22% lipid (Spolaore et al., 2006). More than 100 *Chlorella* species have been named since the description of the type species *Chlorella vulgaris* Beijerinck in 1890. These taxa have been described from freshwater, marine, and edaphic habitats or as endosymbionts (Bock et al., 2011).



Picture 1. Microscopic view of six microalgae strains used in the experiment, genus *Dictyosphaerium* (D36 and D37), genus *Tribonema* (T50) and genus *Chlorella* (C63, C71 and C72), respectively (magnification 40x).

A response to D/N cycle and CAL of six microalgae strains isolated from terrestrial habitats was compared. Outside the visible spectrum in the infrared area on wavelength of 750 nm the density of the algal cell growth was measured. The results showed significant differences in terms of algal strains growth rate between the two light sources. Genus *Tribonema* (Fig. 1) showed significantly better growing dynamics under CAL, relative to D/N cycle. It could be due to its shape, because it was the only filamentous strain involved in the assay, therefore reaction to the different light exposure regimes varied in relation to other strains. The specific growth rate is mainly dependent on algal species, light intensity and temperature (Carlsson et al., 2007).

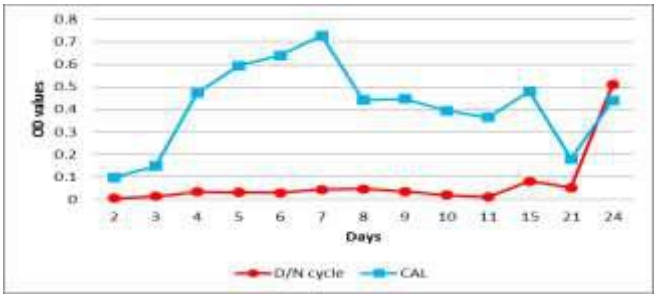


Fig. 1. Growth diagram of T50 monitored for 24 days under D/N cycle and CAL.

Terrestrial microalgae are accustomed to natural lighting with a day and night shift. Grown in their natural environment, photoautotrophic microorganisms show stable increase of the levels of enzymes and metabolites involved in cell division and carbon fixation. Under the CAL, all of three *Chlorella* strains (C63, C71 and C72) showed faster initial growth and entered the exponential phase sooner, compared to other investigated strains (Fig. 2, 3 and 4). Faster initial growth indicates better physiological adaptation of the cell metabolism to growth in induction (lag) phase. These strains proved to be the most resistant, although it is a terrestrial species that naturally develops in the scarcity of light. Light is the source of energy and light

intensity plays an important role that requirement to light substantially dependent on the culture depth and the density of the algal culture (Barsanti and Gualtieri, 2014). The optical density increases with higher light intensity. According to Fatemeh and Mohsen (2016), the best growth of *C. vulgaris* was obtained in lux 650 as well as OD values indicated rapid growth with addition amount of lux.

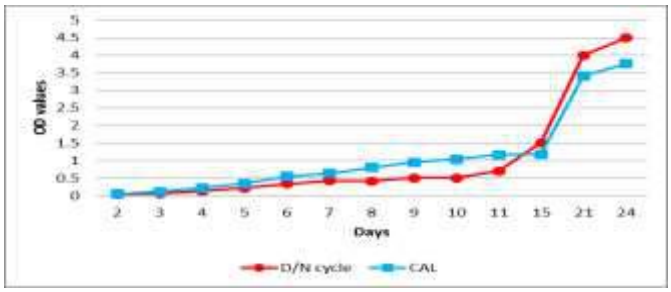

Fig. 2. Growth diagram of C63 monitored for 24 days under D/N cycle and CAL.

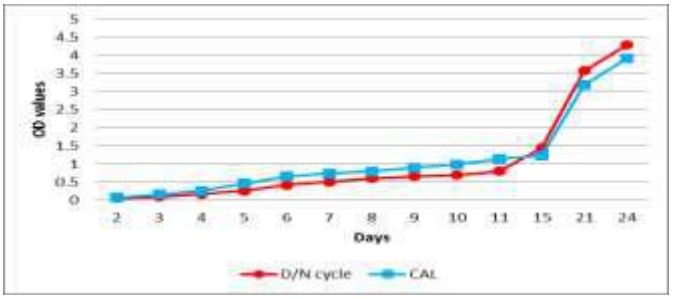

Fig. 3. Growth diagram of C71 monitored for 24 days under D/N cycle and CAL.

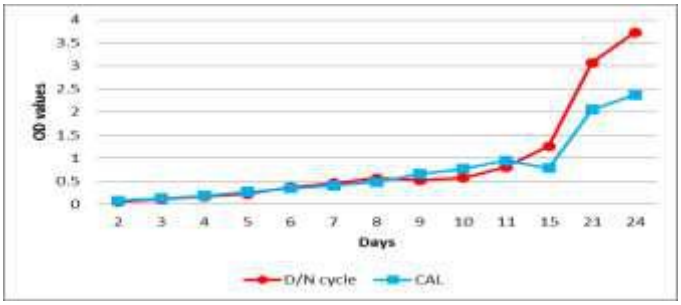

Fig. 4. Growth diagram of C72 monitored for 24 days under D/N cycle and CAL.

Round and coccoid shape strains showed slower but uniformous entry into the exponential phase and greater total OD values at the end of the examined period under natural lighting. As well as in the previous case, strains of the genus *Dictyosphaerium* showed uniform growth in both cases (under D/N cycle and CAL) but at the end of examined period Fig. 5 and 6 shows greater OD values strains cultivated under the D/N cycle. Light intensity and photoperiod are the most important factors for growth rate and biomass composition (Khoeyi et al., 2012). In phase of declining growth rate, many factors such as; nutrients, light, pH, carbon dioxide or other physical and chemical factors limited the microalgae growth and the cell division to be down slow (Carlsson et al., 2007).

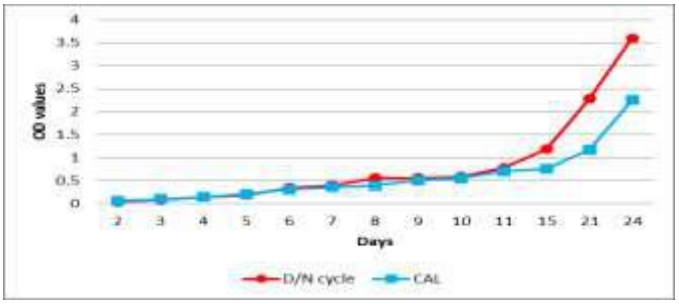

Fig. 5. Growth diagram of D36 monitored for 24 days under D/N cycle and CAL.

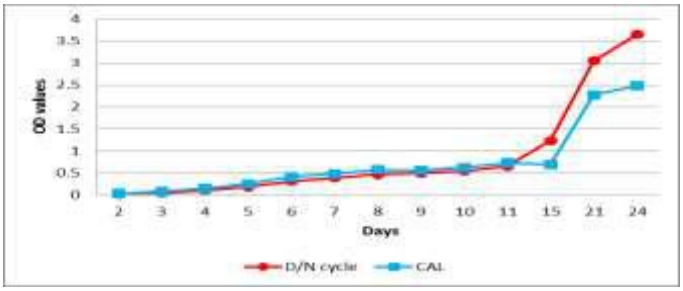

Fig. 6. Growth diagram of D37 monitored for 24 days under D/N cycle and CAL.

Conclusions

A microalgae with optimum growth and productivity at moderate light intensity has great advantage over others. In general, artificial light positively influences algal growth, but in order to achieve economically optimal growth efficiency, rather than maximum efficiency, it is advisable to use natural light conditions in algal biomass production, both in small and large scale cultivation systems.

Abstract

In vineyard of King Peter I Karadjordjevic-Royal Winery at Oplenac-Topola municipality in Serbia and laboratories of the Faculty of Agriculture at the University of Belgrade, varieties Cabernet sauvignone and Sauvignone blanc were examined on winter degree bud freezing. The aim of research was to test Cabernet Sauvignon and Sauvignon blanc cultivars during two years on degree resistance to low negative temperatures. Test carried out with one-year-old shoots in chamber, in three terms on december 15th, january 15th and february 15th at three different temperatures -15, -25 and -20°C. Conditions in chamber were identical to the external conditions. The highest resistance was shown for both varieties in the second testing term. Sauvignone blanc had the highest percent of partially frozen buds in first term, while for Cabernet sauvignone the highest percent of partially frozen buds was recorded in the third term. Statistical significance founded for percent of partially frozen buds were it was significant influence of interaction of variety*treatment.

Key words: *resistance, buds, freezing, Cabernet Sauvignon, Sauvignone blanc*

Introduction

Grapevine is one of the most important agricultural crops, with 56% of world's largest area is the most spread in Europe (Casstelluci, 2013). In overall assortment Cabernet Sauvignon is one of the most widespread red wine varieties. Due to expressed ecological adaptability were cultivated variety in 43 world countries, while Sauvignon blanc is cultivated in 31 countries. By statistical data percent of areas which is covered by Cabernet Sauvignon is the biggest overall cultivated assortment in the world and occupies the first place, and Sauvignone blanc is on fourth place (Fregoni, 2010).

Frost is limiting abiotic factor for grapevines growing. The greatest damage vines had from winter frosts, while minor damage is caused by early autumn and late spring frosts. Temperature decreasing during autumn and optimum shoot preparation affect good frost resistance (Jackson, 2008; Nakalamić and Marković, 2009).

Vine resistance to low winter temperatures is required with genetic basis and variety origin, growing condition, selection and terrain exposure, choice of variety, applied growing tecnology, etc. In order to increase variety resistance to low winter temperatures, it is important late budbreake, high fertility and regeneration buds capacity in case of freezing (Marković, 2012).

By Žunić et al. (2010) the highest resistance to low winter temperatures is characteristic for varieties from *Proles occidentalis,* which also belong varieties Cabernet sauvignon and Sauvignon blanc. Clones of these varieties had special resistance to low winter temperatures. On the other hand, long-term frosts can cause significant buds damage, which can influence grape (Ribereau-Gayon et al., 2006) and wine quality, but also growing in the current year and especially the young shoots (Lisek, 2009).

Material and methods

Experiment carried out (2009/10 and 2010/11 year) in vineyard of King Peter I Karađorđević foundation at Oplenac (Royal Winery at Oplenca). Vineyards with Cabernet sauvignon and Sauvignon blanc are situated at altitude of 250 m above sea level, belonging to Sumadijsko-velikomoravski vine region in Serbia. Vineyard planted with Sauvignon blanc (clone R 3) covers area of 3.7 ha, located on cadastral parcel KP 730/2 which belongs to cadastral municipality of Bozurnja. Geographically is positioned on GPS coordinates N 44° 14' 4" and E 20° 41' 15". Research on Cabernet sauvignon (clone ISV-FV 5) was carried out on cadastral parcel KP 629, cover area of 0.55 ha geographically is positioned on GPS coordinates N 44° 14' 35" and E 20° 41' 22". In both cases was formed training system with Guyot pruning system, spacing between rows is 2.70 m and 1 m in row.

Test of buds resistance to low temperatures was carried out exposing one-year-old shoots to low temperatures in chamber. On selecting of freezing regime aim was that conditions for cooling in chamber must be similar to external conditions.

For testing from vineyard was sampled representative sample of 10 shots with 10 buds. Shoots were transferred to chamber where they were subjected to temperature of -5°C for 24 hours. After 24 h temperature in chamber was reduced every hour for 3°C to final temperature. At that temperature samples were kept for 12 hours, after which they taken out of chamber and left at room temperature 5 days. After five days by making a cross-section of buds was examined level of freezing of central and second bud. Number and percent of non frozen, partly frozen and completely frozen buds was determined.

Resistance of grapevine buds is not same during whole winter period, test was carried out in three terms during 2009/10 and 2010/11: December 15th, January 15th and February 15th at three different temperatures -15, -25 and - 20°C whereby to determine resistance degree of Sauvignon blanc and Cabernet Sauvignon at the beginning, mid and late winter period.

The IBM SPSS Statistics 2.0 (statistical package for social sciences), Chicago, IL, USA was used for data analysis. For factor influence was used analyze of variance with fixed factors level. In tests a significance level of 0.05 was used. For post-hoc comparisons, Tukey HSD and LSD test were used.

Results and discussion

In 2009/2010 research period both varieties had the highest resistance to low temperatures in the second test period (15.1.). In this term the highest was recorded the bigest percentage non froze buds. After this term Cabernet sauvignon had the highest resistance to frost in the third term-15.2. and finally in the first term-15.12. Sauvignon blanc had opposite variation trend of resistance. After the second term, the first term-15.12 was followed and finally was the third term 15.2. (table 1). During 2010/2011 period, both varieties had same variation trend of resistance to low temperatures, with difference that Sauvignon blanc had a higher percentage of non frozen buds in first term-84%, then in the second-73% and finally in the third term of 43%. Markovic (2001) states that in resistance examination of Cabernet sauvignon buds to freezing, percent of non-frozen buds increasing from december to mid-January. Resistance degree, i.e. percent of non-frozen buds was in a positive correlation with dry matter content in shoots, while percent of frozen buds was in correlation with free water content in shoots.

Wolf and Cook (1994) emphasize that, with adequate temperature regime and monitoring of temperature decreasing in chamber effect of froz as well as in environment can be simulated, and in this way determine resistance degree of variety to low temperatures. By two-factor analysis of variance was founded that in both research year was influence of treatment and interaction of variety*treatment. Therefore, there are further specially compared varieties especially for every treatment and treatments for each variety. This comparison (table 2-3) was carried out by a single-factor analysis of variance (in the comparison of varieties).

Table 1. Average value of percent of non frozen buds

Year	Variety	Term of treatment			Average
		15.12.	15.1.	15.2.

Statistically significant difference between Cabernet sauvignon and Sauvignon blanc was at 15.2. 2009/2010. and 15.12. 2010/2011. years. In both treatments, Sauvignon blanc had higher percent of non-frozen buds compared to Cabernet sauvignon for same period.

In period 2009/10. at Sauvignon blanc was statistically significant difference between following terms: 15.12. and 15.1, while 15.2. does not differ from these two dates. In same period at Cabernet sauvignon was statistically significant difference for term of 15.2. in relation to two remaining dates (which do not differ).

In 2010/11. for Sauvignon blanc was founded statistically significant difference between 15.12. dates and two remaining dates. For Cabernet sauvignon 15.2 is different. from two remaining dates.

During 2009/10 Cabernet sauvignon had the highest percentage of partly frozen buds (36%) in period from 15.12., while Sauvignon blanc had in the third term (15.2), where was determined 45% partly frozen buds (table 4). In 2010/11 was recorded same variation trend.

Using two-factor variance analysis for 2009/2010. and 2010/2011. was faunded same trend variety*treatment interaction (table 5-6).

During 2009/10 both varieties had the highest percent of total frozen buds in period from 15.2., to Sauvignon blanc determined 20% and at Cabernet sauvignon 16% (table 7). Sauvignon blanc showed in all three research periods a low tolerancy to winter temperatures, with a higher percent of frozen buds compared to Cabernet sauvignon.

In 2010/11, percent of total frozen buds to Cabernet sauvignon was significantly lower than Sauvignon blanc. The highest percent of freezing was recorded at 15.2, while in Sauvignon blanc significant freezing was recorded in period from 15.12. and 15.2.

By Lisek (2009; 2012) Sauvignon blanc in conditions of Poland is very sensitive to frost. High frequency of long-lasting frosts causes to Sauvignon blanc up to 96% of total frozen buds, which makes this variety less suitable for growing under long and frequent winter frosts. Cabernet sauvignon shows possibility of adaptation to different climatic conditions as evidenced by fact that it is cultivated in most important world areas, where average annual temperature varies by average of 3.5°C, which for most wine varieties is not adequate (Jones, 2010; Ruml et al., 2012; Markovic et al., 2016 and Vuković et al., 2016).

According to Maletic et al. (2012) variation of agrobiological and technological characteristics of Cabernet sauvignon and Sauvignon blanc is consequence of large varietal

variation and result large number of isolated clones. Variety divergence is expressed to Cabernet sauvignon with more than thirty clones of this variety separated. One part is introduced and cultivated in Serbian vineyards (Žunić et al, 2012).

Table 7. Average percentage of total frozen buds

Year	Variety	Term of treatment			Average
		15.12.	15.1.	15.2.	
2009/10.	Cabernet sauvignon	16.00	13.00	20.00	16.33
	Sauvignon blanc	11.00	8.00	16.00	11.67
	Average	13.50	10.50	18.00	14.00
2010/11.	Cabernet sauvignon	28.00	9.00	26.00	21.00
	Sauvignon blanc	7.00	8.00	25.00	13.33
	Average	17.50	8.50	25.50	17.17

By dual factor analysis of variance did not faunded interaction between variety and treatment, only effect of treatment existed (table 8). In period 2010/11 (15.12) was interaction of variety*treatment.

Table 8. Two-factor variance analysis for 2009/2010. and 2010/2011. year

p=0,05

Conclusion

In research period 2009/2010 and 2010/2011, both varieties had the highest resistance to low temperatures in the second test period (15.1.). In this term was recorded the highest percent of non frozen buds. Sauvignon blanc had the highest percent of frozen buds in period from 15.12, while at Cabernet sauvignon the largest percent of partially frozen buds was recorded in the third test period (15.2.). The highest percent of frozen buds for both varieties was determined at 15.2. In both years of research there was treatment interaction.

Abstract

Natural fiber composites are nowadays used in various engineering applications to increase the strength of a product as well as optimize its weight and cost. One such natural fiber which can be used as a reinforcement material is banana fiber. Banana fiber is produced from the leaves that make up the pseudo-stem of the plant, that is, its stalk or trunk. In the same way as other natural fibers, they contain five basic chemical components, namely cellulose, hemicellulose, lignin, pectin, and certain extractable compounds (vegetable fat, proteins and inorganic salts). Although the Canary Islands is a significant producer and consumer of bananas, the fiber which the plant produces has not been put to much use at all, and, thus, there has been little research into it. The main sectors in which the fiber does have a potential use are those of textiles, paper and plastic. This paper will briefly describe the science of banana fibers and review various methods of banana fiber extraction which are already in existence. The first method is a manual one. There are two chemical methods that can be used to make banana bast fiber. The first comprises an acid treatment of the banana stalk, and the second consists in a basic treatment with lime. Another method use steam explosion-based degumming. Another way of obtaining banana fibers is by employing the biological process of retting. Finally, there is also a variety of machines that can be used to extract banana fibers.

Keywords: *Waste, banana, fiber, extraction, Spain.*

Introduction

Banana fiber is produced from the leaves of the banana tree. It is a bast fibre and based on its dry weight, it is composed of cellulose (40-90), semicellulose (1-30), lignin (1-35), pectin (1-2) and water soluble matter, namely lipids, proteins and inorganic salts) (2-3 weight %) (Wu *et al*., 2005; Albinante *et al*., 2012). Lignin is one of the most abundant natural polymers and acts as a cementing agent to bind the matrix of cellulose and semicellulose fibers together into a rigid structure. Due to its chemical structure, it being a complex non-carbohydrate aromatic polyphenol (Figure 1), it is highly resistant to decomposition and oxidation (Albinante *et al*., 2012). In their study, Ganan *et al*. (2004a) describe the hierarchical microstructural ordering present in banana fiber bundles in both the bundle surface and the inner region. The chemical composition of the banana fiber bundles was investigated using a FTIR spectroscopy. It was observed that the main structures, which form the outer walls of the bundle, are composed of hemicellulose and pectins. In addition, hierarchical helicoidal ordering on the bundle surface as well as orientation on the longitudinal axis of the bundle were observed using Optical Microscopy (OM) and Scanning Electron Microscopy (SEM), for 3-4 mm surface fibers and 10-15 mm inner elementary fibers, respectively (Ganan *et al*., 2004a).

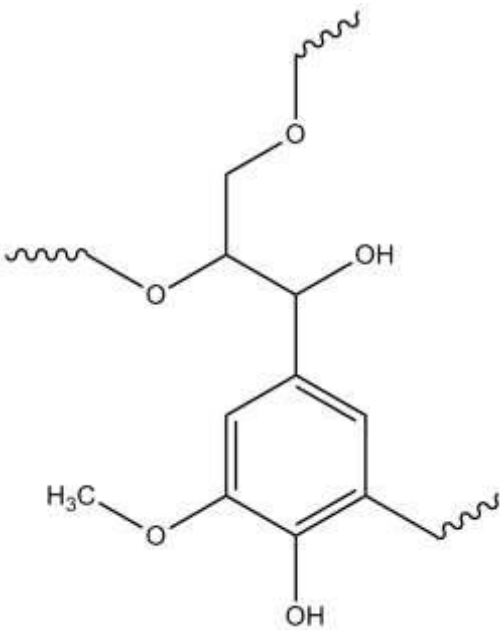

Figure 1. Phenyl propane units of lignin.

The following studies demonstrate the wide range of possibilities that already exist for exploiting banana fiber. Yan and Lin (2005) describe a process for producing paper and paper products, which possess high tensile strength, high bending strength, good water resistance and high density while Burton (2008) refers to a technique which involves laying cross-fibers across the grain of a paper sheet, to increase tear resistance. Nachane and Shanmugam, (2014a) talk about a carding machine which is capable of efficiently carding previously unspinnable banana pseudostem fibers into fine spinnable textile grade fibers as well as a machine in which raw fibres can be straightened out and converted into a fiber of a thickness suitable for yarn formation (Nachane and Shanmugam, 2014b). Wu (2014) points out that it is possible to combine banana fiber with other natural fibers, including jute and cotton fiber, to make a kind of multi-functional fiber and, finally, **Datta** *et al*., (2012) discuss the use of raw materials, such as banana fiber, to produce cheap membranes for wastewater treatment.

Material and Methods

The data in this paper was compiled from a number of authentic online data bases, including Chemical Abstracts, now part of Scifinder. A comprehensive bibliographic search was carried out using the keywords "fiber and banana", refined with the word "extraction". Once the results were obtained, the duplicates were excluded.

Results and Discussion

Banana bast fibers are firm in structure and wear-resistant. Their moisture absorption and air permeability is good, inhibiting bacteria and preventing mildew. They can be spun into yarn, and used to make material which is environmentally friendly and a non-irritant to the skin. This means it can be used for clothing or, alternatively, made into products such as ropes, handbags, and doormats. A number of different ways of preparing the banana fibers will now be described in detail.

The first method is a manual one, involving banana fibers with an average fiber length of 10-50 mm, and an average fineness of 0.5-80 dtex. Firstly, the epidermis and bark are removed from a harvested banana stem to leave a bundle of fibers. These are dried, and then treated with 3% caustic soda at 130°C at high pressure. They are then washed again and the soda

neutralized. After drying out, they are cut to give a staple fiber with an average length of 35 mm (Takamori and Kawaharazaki, 2010).

There are two chemical methods that can be used to make banana bast fiber. The first comprises an acid pretreatment of the banana stalk with 0.1-0.4 % aqueous H_2SO_4, at a ratio of 30-50:1 and 20-50 °C for one to two hours. After this, the stem is boiled in a mixed aqueous solution of sodium hydroxide, sodium sulfite and sodium pyrophosphate for one to three hours and then stewed in a mixed aqueous solution of sodium hydroxide and industrial soap at 90-98 °C for a further one to three hours. It is then bleached in 2-5 wt % sodium hypochlorite at 5-25 °C for 5 to 12 minutes, acid washed in 0.1-0.2 % aqueous H_2SO_4 solution at 5-25 °C for 5 to 10 minutes, and then drained and dried (Wu *et al*., 2005). Another chemical method for extracting fibers from banana stalks consists of dissolving quick lime in 20-25 °C water to obtain a 3 % lime solution, which the banana stalks are placed into. When the pH value reaches 3.5-4.5, the liquid is drained and the banana stalks are washed to remove the impurities, and sun-dried. Then, the product is soaked in a 3% sodium hypochlorite solution, bleached, and sun-dried. It is then treated with a 1% N-octadecyl N'-ethylene urea solution at 80°C, cooled to room temperature, and then sun-dried. The fiber hemp which is produced weighs little and gives high water-absorption performance (Huang, 2008).

Another method for preparing fibers from the banana stalks and leaves using steam explosion-based degumming was described by Chen and Peng (2011). The advantages of this method are that it is inexpensive, causes no pollution, has a high yield, and offers a high quality product. To begin with, the stalks and leaves are cut into 5-15 cm. long segments, and then subjected to steam explosion under 1.0-1.8 MPa for 1 to 8 minutes, after which they are rinsed with water 10 to 20 times to remove the degraded pectin, and hemicellulose. Finally, they are bleached twice at 50-60 °C and at a solid - liquid ratio of 1:(10-20) for 20 to 40 minutes each time. The first bleaching solution is composed of: 10 g L^{-1} Na_2SiO_3, 10 g L^{-1} H_2O_2, and 10 g L^{-1} NaOH whereas the second bleaching solution consists of: 5 g L^{-1} Na_2SiO_3, 5 g L^{-1} H_2O_2, and 5 g L^{-1} NaOH. The steam explosion treatment can degrade over 90% of the pectin and hemicellulose and degrade some of the lignin in the banana stalks and leaves as well as completely separate the fiber bundles from other components. In addition, the steam explosion treatment splits the banana fibers into loose structures, thus facilitating the bleaching and oiling. It also loosens the banana fibers and increases their quality (Chen and Peng, 2011).

A similar method for extracting and degumming banana fibers by steam explosion was described by Sheng *et al*. (2011), who cite the same advantages as above. It comprised the following steps: the freshly cut banana stalks are placed in a steam explosion tank, and a steam explosion is performed under 1.20-1.60 MPa for 1-2 minutes. The stalks are then decompressed, washed in water, and dehydrated to obtain coarse banana fibers, which are soaked in 10-20 g L^{-1} NaOH at room temperature for 24 to 48 hours. They are then washed in water to be neutralized, and dehydrated, after which they are placed in the steam explosion tank again, under 1.35-1.55 MPa for 1-2 minutes, with the water content at 20-40 %. Once again the coarse banana fibers are decompressed immediately, washed in water, and dehydrated before being bleached in a bleaching solution (1-1.6 % Na_2SiO_3, 2-2.8 % NaOH, and 2-2.9 % H_2O_2) at 55-62 °C and 1:(14-18) ratio for 1 to 2 hours, rinsed and then bleached again for the same amount of time in another bleaching solution (1-3 % Na_2SiO_3, 1 % NaOH, and 1-1.6 % H_2O_2) at the higher temperature of 60-68 °C and 1:(15-19). After then being washed in water, and oiled and dried, the white banana fibers are loosened, and carded (Sheng *et al*., 2011).

Another way of obtaining banana fibers is by employing the biological process of retting. The action of micro-organisms and moisture on plants can dissolve or rot away much of the cellular tissues and pectins surrounding bast-fiber bundles, thereby facilitating separation of

the fiber from the stem (Editors of Encyclopaedia Britannica, 2009). Depending on the exposure time, the fiber bundle configuration presents small variations in composition, the main changes being related to hemicellulose and pectin, as they are found in the outer walls of the bundle. With an increase in exposure time, the fiber bundle walls lose integrity, as reflected in their mechanical behavior (Ganan *et al*., 2004a,b). Banana bast fibers can also be prepared by biological degumming (Li *et al*., 2010). The preparation method comprises sterilizing, removing impurities, inoculating, fermenting, water washing, adding caustic soda, boiling for 20-30 minutes, water washing, adding hydrogen peroxide, and then boiling for 20-30 minutes, followed by inactivation, stamping, and post-treatment. The obtained banana bast fiber is soft, loose and odorless. It is 80-200 mm in length, with a fiber count of 300-500 Nm. The bundle fiber breakage strength is 3.5-5.0 g D^{-1}, and it has a residual gum rate of 1.5-3.2 %. There is also a variety of machines that can be used to extract banana fibers and some of these will be described below. The first one comprises a chassis assembly consisting of a chassis and a pair of pneumatic tires attached to an axle, which is secured to a pair of leaf springs located under the chassis. The chassis has a towing bar, and telescopic legs, and longitudinal angular bars. There are two engine bases, and two decorticating frames, each of which has an upper member, a vertical member, a slanted member, and a base member. These parts are fixed together, forming a trapezoidal shape, and there is a stabilizer plate welded on perpendicularly near the upper portion of the slanted member. An anvil and chute assembly, consisting of a pair of swing arms, is pivotally attached to the chassis. There is a retainer plate fixed to the upper portion of the swing arms, as well as a pair of retainer nuts welded to the retainer plate, with a pair of bolt stabilizers passing through the retainer nut and, thus, the retainer plate can be adjusted. There is also a pair of lock nuts on the bolt stabilizers. There is an anvil and a bracket connected to the swing arms, with a pair of adjuster bolts on the bracket. In addition, there is a circular spring plate fixed to the adjuster bolt, which has a compression spring coiling around it (Valenzuela *et al*., 2007).

Another machine, which was designed and developed in India for the commercial extraction of fiber from the previously unused waste portions of banana plants, such as pseudo-stems, peduncles, and leafstalks, and which is considered to be user friendly and inexpensive, is the Central Tobacco Research Institute (CTRI) Banana Fiber Extractor Machine. This machine consists of a rigid frame, on which a roller, consisting of twenty seven mild steel or stainless steel horizontal blades (6 mm size) with blunt edges, rotates on a free moving shaft. The roller can be driven by a standard one horse power single phase electric motor, using a belt and pulley arrangement, which is fixed over the rigid frame. The advantages of the machine are that it can reduce drudgery and increase fiber production by 20-fold as compared to the manual process. The extraction of fibers means that an additional net income of 12,000 Indian rupees per hectare is guaranteed to the banana cultivators (Sudhakar *et al*., 2010).

A further invention is an automated mechanical tool which can be used to separate fibers from the banana sheath in an efficient and non-cumbersome manner, according to Murugesan (2013). It has between 16 and 20 serrations along one edge, with dimensions of 2 x 1.5 cms. By striking the plant across the serrations, it is possible to extract the fibers.

Yang and Qian (2017) describe another recent invention for banana stalk fiber extraction, which consists of a rack, with a motor affixed to it. The apparatus also has a rotating shaft, which is connected to the rack, with two turntables and a blade. This apparatus uses the force of natural spring compression to extract the fibers. Zhang (2017) refers to yet another machine which works by feeding the banana stalks between an upper and lower rack. A transmission device allows the racks to be spun and the fibers are stripped from the stalk as the machine rotates. Not only does the impurity rate appear to be low, particularly since insects caught in the fiber fragments are shaken loose, but the fiber extraction is considered to be efficient and

the extraction of the fibers, which can then be sold in addition to the bananas themselves, enhances the income of the banana farmers.

Conclusion

Natural banana fibers can be extracted in a number of different ways, either manually, chemically, biologically, using steam explosion-based degumming, or using modern machines. Each method has its own benefits and drawbacks, depending on the amount of fiber produced or the quality and properties of the fiber bundles obtained. It is hoped that the application of the banana fiber extraction methodology in the Canaries could benefit the local agricultural economy as it is already doing in other parts of the world.

ASSESSMENT OF GENETIC SIMILARITY AMONG THE PROGENIES OF THREE APPLE SEEDLING ROOTSTOCKS BY USING SSR MARKERS

Bayan M. MUZHER*, Ola T. ALHALABI

General Commission for Scientific Agricultural Research, Syrian Arab Republic
*Corresponding author:bmuzher@hotmail.com

Abstract

This investigation was done at the General Commission for Scientific Agriculture Research (GCSAR) – Pome and Grapevine Division in Sweida province (Syrian Arab Republic) during 2012 and 2013, in order to study the genetic similarity among 10 seedlings and the mother plant of three different seedling rootstock genotypes (A, B and C), which have been included in the breeding programme for apple rootstocks, by using 17 SSR markers. The results revealed the ability of 16 primer pairs to amplify alleles in all studied progenies and mother plants. The highest polymorphism was observed in progeny raised from the genotype B (87.1 %), followed by the progenies of genotypes A and C (80% and 78.1%, respectively). Genetic similarity of both genotypes A and C with their progenies were more than 0.5 in each of them, while in genotype B with its progeny was more than 0.5 in 8 seedlings, whereas genetic similarity among the progeny of each genotype (A, B and C) were 0.53, 0.53 and 0.58, respectively. Cluster analysis divided the progeny of genotype A into two groups and progenies of B and C genotypes into three groups. The expected heterozygosity (He) was 0.39 in each studied genotype, and the observed heterozygosity (Ho) was 0.27, 0.3 and 0.5 in A, B and C, respectively. On the other hand, the results showed high efficiency of some markers to detect genetic differences within genotypes, such as CH01H02, Hi04g05, O2b1 and CH01f02. These results showed the degree of homogeneity among the seedlings produced by each genotype, and the importance of using SSR markers in apple rootstock breeding programme.

Keywords: *Malus, rootstock, genotyping, microsatellites.*

Introduction

Apple rootstock breeding programme consists of essential steps represent in determining the objectives related to actual problems such as the age of trees, propagation ability, compatibility between rootstock and scion, in addition to the productivity (Cummins and Aldwinckle, 1995). However, apple rootstock breeding programmes are worldwide in most countries producing apple depending on their local own needs such as winter hardness tolerance , dwarfing, pest resistance, and precocity, like as America (Johanson *et al*., 2001), UK (Webster and Wertheim, 2003), Germany (Fischer, 1997), Poland (Jakubowski and Zagaji, 2000), Latvia (Bite and Lepsis, 2004; Rubauskis and Skrivele, 2007), and Russia (Bite and Lepsis, 2007). In Syria apple rootstock breeding programme is focused on the selection of resistant rootstock to woolly apple aphid and establishing a source for seedling rootstocks (Al-Halabi *et al.,* 2012). Molecular markers are an important tools for discrimination of species and different plant genotypes (Kiraly *et al*., 2008), particularly in woody plants (Wunsch and Hormaza, 2002). Also, molecular markers are used in apple rootstock breeding programmes to get accurate characterization for produced rootstocks (Gupta *et al*., 2004). Simple sequence repeat (SSR) markers have many properties over the other markers, they are co-dominant markers, have many alleles per locus, very available in genome, and can be used for cultivar identification, pedigree analysis, genetic diversity and genetic mapping (Lu *et al*., 2010). The genetic information about the wild *Malus* species of apple rootstocks are not well defined, thus 86 SSR markers were used to identify commercial rootstocks with their wild parents (Fazio and Baldo, 2005). However, SSR markers are widely used for apple genetic studies

(Farrokhi *et al*., 2011; Muzher and Al Halabi, 2017). This study was carried out to determine the genetic similarity between seedlings with their mother plants using SSR markers in order to select the best genotype as a source for seeds in apple rootstock breeding programme in Syria.

Materials and methods

The present investigation was carried out at Pome and Grapevine Division – GCSAR in Sweida province, which is located at 1,525 m altitude in the south of Syrian Arab Republic, during 2012–2013.

Plant material

Three apple rootstock genotypes (A, B and C) which derived from apple rootstock breeding programme, and their progenies (10 seedlings from each genotype) were used in this study.

DNA extraction

Genomic DNA was extracted from young leaves of assessed genotypes, using CTAB method described in Porebski *et al*. (1997).

PCR amplification

PCR amplifications were carried out by the using 17 primer pairs developed from apple genome as follows: 10 primer pairs (Hi-SSR) were developed by Silverberg *et al*. (2006), 6 primer pairs (CH-SSR) by Gianfranschi *et al*. (1998), and one primer pairs (O2b1) by Guilford *et al.* (1997).

The PCR reaction was performed in a 10 µl volume with 1 µl 10 X buffer + 1 µl dNTPs + 1 µl forward primer + 1 µl reverse primer + 3 µl DNA + 0.1 µl taq + 2.9 µl dH_2O. The cycling profile consisted of an initial denaturation step of 3 min at 94ºC, followed by 35 cycles of denaturation of 30 s at 94ºC, annealing of 30 s at an optimal temperature for each primer combination (55–58ºC) and extension of 1min at 72ºC, with a final 5-min extension step at 72ºC.

Visualization of the PCR products

The PCR products were detected by electrophoresis on 2% agarose gel in 1X TBE buffer, stained with ethidium bromide and visualized by gel documentation. The molecular weight of obtained alleles was estimated by Bioprofil-Bio-1D software using 100 bp DNA ladder (Gene direX, USA)

Data analysis

All alleles were scored as present alleles (1) and the absent one (0), then polymorphism calculated as % of polymorphic alleles. Genetic similarity (GS) was estimated according to Jaccard coefficient (Jaccard, 1908). Dendrogram was clustered by cluster analysis using UPGMA method (unweighted pair-group method using arithmetic averages) by Past software. Expected Heterozygosity (He) was calculated according to Lorenzo *et al*. (2007). While the observed Heterozygosity (Ho) was calculated according to Wunsch and Hormaza (2007), and marker index (MI) according to Powell *et al*. (1996).

Results and discussion

SSR primer pairs (16 pairs) revealed 30 alleles in genotype A with its progenies, of which 24 alleles were polymorphic (80%), the number of alleles ranged between 1 and 4 in different loci, with an average 1.88 alleles per locus; concerning genotype B with its progenies, 31 alleles were revealed, of which 27 alleles were polymorphic (87.1%), the number of alleles ranged between 1 and 3 in different loci, with an average 1.93 alleles per locus; while 32 alleles in genotype C with its progenies were revealed, of which 25 alleles were polymorphic (78.1%), the number of alleles ranged between 1 and 3 in different loci, with an average 2 alleles per locus (Table 1). In addition, the most efficient SSR markers were CH01H02, Hi04g05, Hi09a01, O2b1 and CH01f02 (Figure 1). On the other hand, the primer pair O2b1 informatively showed co-dominant alleles in the mother plant of each studied genotype.

Obtained results confirmed that these genotypes are hybrids, and the progeny of genotype B is the most varied among studied genotypes. The produced alleles size was between 92 bp and 265 bp (Table 1), and the size of all alleles was in agreement with the findings of Guilford *et al*. (1997), Gianfranschi *et al*. (1998) and Silfverberg *et al.* (2006). Zhang *et al*. (2012) evaluated genetic diversity between wild apple species and commercial cultivars using 19 SSR primer pairs, and found that the number of alleles was between 2 and 11 alleles in different loci. Also, the results of this investigation were consistent with results from Farrokhi *et al*. (2011), who studied the genetic variation among Iranian apple cultivars by using 16 SSRs and found that the number of alleles ranged from 2 to 5 alleles in different loci, with an average 2.8 alleles per locus.

Table 1. Number of alleles and polymorphic alleles, polymorphism (%), and allele size (bp) produced by SSR primer pairs in studied genotypes with their progenies.

Locus	**Alleles number**			**Polymorphic alleles**			**Polymorphism %**			**Allele size (bp)**

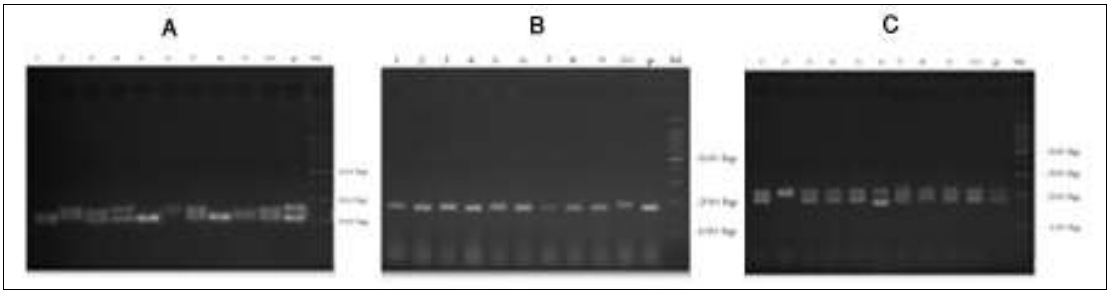

Figure 1. Alleles profile of SSR primer pairs O2b1, Hi09a01 and CH01F02 in A, B and C genotypes, respectively; M: Marker 100 bp ladder; the numbers from 1 to 10 represents seedlings of each genotype; P: the mother plant.

The highest genetic similarity between genotype A and its progenies was 0.84, while the lowest one was 0.52, on the other hand, the average genetic similarity among the progenies of genotype A was (0.53), which reflected sufficient genetic similarity between genotype A and its progenies; and among the progenies according to Zaied *et al*. (2006). The genetic similarity of 8 out of 10 seedlings derived from genotype B with their mother plant was more than 0.50, however the highest genetic similarity between genotype B and its progenies was 0.68, and the lowest one was 0.40, on the other hand the average genetic similarity among the progenies of genotype B was 0.53. Seedlings of genotype C distinguished by high genetic similarity with their mother plant (the highest 0.81; the lowest 0.61), as well as the average genetic similarity among the progenies was 0.58. These results showed the degree of homogeneity among the progenies with their mother plants especially in genotypes A and C, which is considered as essential step in selecting seedling rootstocks. These results were in agreement with Al-Halabi and Muzher (2015), who reported that the highest genetic similarity between Sukari 2 genotype and its progenies was 0.81.

Cluster analysis divided seedlings of genotype A and the mother plant into two clusters (I cluster – six seedlings and the mother plant; II cluster – four seedlings; Figure 2). Cluster analysis grouped seedlings of genotype B and the mother plant into three clusters, i.e. the first cluster with four seedlings and the mother plant, the second cluster with five seedlings and the third cluster with one seedling (Figure 2). Regarding seedlings of genotype C and the mother plant, three clusters were obtained (I cluster – five seedlings and the mother plant; II cluster – four seedlings; III cluster – one seedling; Figure 2).

The expected heterozygosity (He) was the same (0.39) in all studied genotypes with their progenies, while the genotype C revealed with its progeny the highest observed heterozygosity (Ho) which was 0.5, followed by 0.3 and 0.27 in genotypes B and A with their progenies, respectively. He and Ho values indicated to the low degree of genetic variation within the studied genotypes, which were lower than the literature reviews using SSR markers on apple (Wunsch and Hormaza, 2007; Sikorskaite *et al*., 2012). The highest MI value was in genotype B with its progenies (10.53), followed by genotypes C and A with their progenies (9.75 and 9.36, respectively). This index was correlated with the number of polymorphic alleles and He value reported by Muzher (2004).

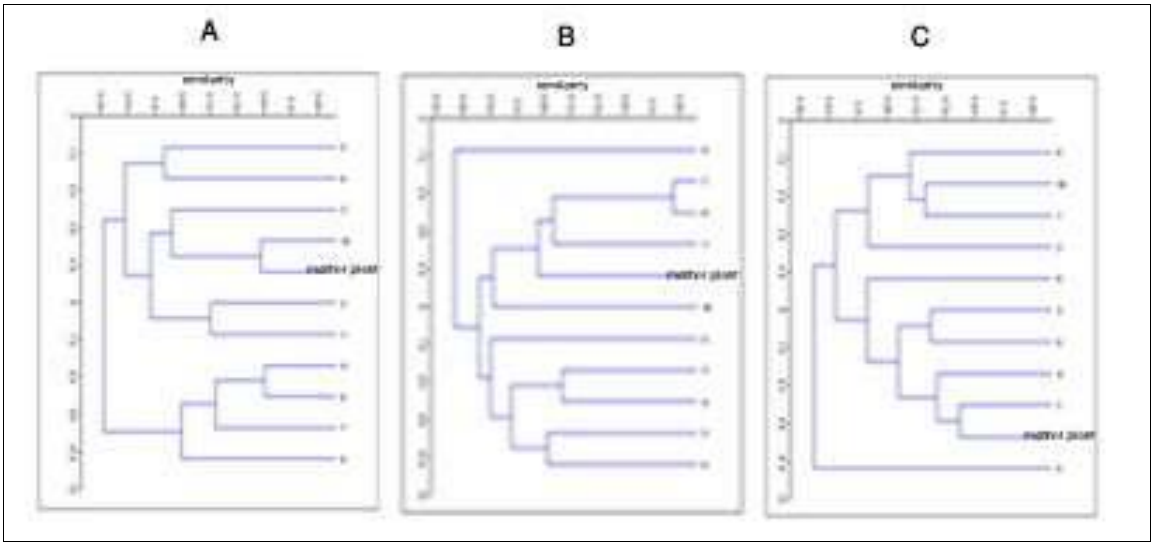

Figure 2. Cluster analysis as derived from SSR marker, for the seedlings and their mother plants (A, B and C genotypes).

Conclusion

The results of studied genotypes and their progenies using SSR markers showed that the genotypes A and C gave more homogeneous seedlings in comparison to genotype B. Therefore, genotypes A and C can be recommended as a source for seed production. In addition, the obtained results illustrated the importance of using SSR markers as an efficient tool for discrimination relative individuals in breeding programmes.

INFLUENCE OF STRATIFICATION PERIODS AND CULTURE MEDIUMS ON THE GERMINATION OF APPLE ROOTSTOCK SEEDS

Ola T. ALHALABI*, Bayan M. MUZHER

General Commission for Scientific Agricultural Research, Syria
*Corresponding author: ola_halabi@msn.com

Abstract

This investigation was conducted at General Commission for Scientific Agriculture Research – Pome and Grapevine Division in Sweida Province (Syria) during 2014 – 2015, to study the ability of apple seedswhich derivedfromthe hybrid genotype (HS) and seedling rootstock (B) in apple rootstock breeding program in addition to 'Golden Delicious' variety (GD) to germinate at alternative periods 45, 60 and 90 days of cold stratification at 4°C in different mediums Murashige-Skoog, Murashige-Skoog + 3% sucrose, sand, and sand + 3% sucrose. The results showed that the highest seed germination percentage in HS(87.5% and 80%)was obtained after 60 days of stratification in Murashige-Skoog + 3% sucrose and sand respectively. In B rootstock the highest seed germination percentage was 88.7% after 90 days' stratification in Murashige-Skoog + 3% sucrose, followed by 85% in sand + 3% sucrose after 60 days. However, the highest seed germination percentage in GD cultivar was 87.5% after 60 and 90 days' stratification in Murashige-Skoog and sand + 3% sucrose respectively. The mean time for germination was between 2.7 and 9 days depending on the studied treatments. These results illustrated the importance of determining the best cold stratification period and stratification mediumfor each genotype seeds to produce high apple seedlings in breeding programs and nurseries.

Keywords: *apple, cold stratification, seed germination.*

Introduction

Many seeds of plant species need to incubate at low temperature after moistening to achieve germination and this procedure is called stratification. The period of stratification varies between plant species either between cultivars as well (Daskalyuk and Toma, 1994).On the other hand, the length of the stratification period depends on the environmental conditions during seed formation and ripening (Lewandowski and Zurawicz, 2009; Militaru*et al*.,2009).

Germination consists of all processes which start from absorbing water by the dormant dry seed, and the germination is complete when the radicle penetrates the structures surrounding the embryo (Bewley, 1997). By definition, dormancy of apple seeds is caused by many inhibitors preventing germination process, which considered as compound dormancy (physical and physiological). Physiological dormancy is the most common type of dormancy, and it can be divided into deep, intermediate and non-deep levels, of which the non-deep level accounts for a substantial proportion of all dormant seeds (Graeber *et al.* 2012 ; Baskin and Baskin 2014).Seed coat and embryo coat are responsible of physical dormancy, while physiological dormancy is related to physiological state of embryo (Lewak, 1981; Daskalyuk, 2002).

Embryo dormancy can be removed completely by low temperature (5° C is optimal),According to Bakke *et al*. (1926), embryo hydration is essential to eliminate seed dormancy. However, no factor can affect the removal of dormancy without partial hydration at least for embryo. The depth of seed dormancy is determined by the cooled period needed to germinate the seeds soaked in water, and the optimal temperature for germination is 18° C(Lewak, 2011).

The levels of abscisic acid (ABA) and gibberellin (GA) were determined in apple seeds for hybridizations between different cultivars, and all seeds showed similar changes in ABA and

GA levels during 80 days of stratification (Lee and Looney, 1978).BartheandBulard (1983) stated that ABA plays an important role in embryo dormancy of apple seeds, and there is a relation between dormancy depth and the accumulated amount of ABA.
Locules serve as protectors for seeds as long as the seeds remain in the fruits, due to unknown inhibitor (s) preventing germination(WanandDennis,1992). Pauwels*etal.* (1999) studied seed germination characters useful in apple breeding program, and they found that the cultivar has an obvious influence in the time of seed germination. In hybrids the female parent effected on the time of seed germination whilst the male parent had a little influence, and there was insignificant association between bud break and seed germination. In a study of plant seeds which were extracted from ripen stored fruits of 12 apple hybrids at 2-3°C for 59 days, then transferred to an unheated plastic tunnel, germination percentage was 86.7%, time for germination 2.5-4.2 days, and this provides a high production of seedlings in a breeding process during a short time after stratification (Pitera and Odziemkowski, 2006).
In Syria, the dependence on seedling rootstocks isthe commonapproach in most regions where apple trees are grown, and apple rootstock breeding program is aimed to select the seedling rootstocks most suitable for Syrian conditions (Al-Halabi and Muzher, 2015). This research was conducted to study the effect of stratification periods and culture mediums on germination of apple seeds for some genotypes from apple rootstock breeding program in addition to 'Golden Delicious' variety.

Materials and methods

This investigation was achieved during 2014-2015at Pome and Grapevine Division- GCSAR in Sweida province which is located in the south of Syria at 1525 m altitude.
Apple seeds from hybrid genotype (HS) between 'MM106' rootstock and the local apple cultivar 'Sukari', and seedling rootstock (B) from apple rootstock breeding program in addition to 'Golden Delicious' variety (GD).
Seeds for each genotype were put in different mediums after surface sterilized: (I)25ml of Murashige-Skoog with 0.8 agar without hormones and vitamins, (II)25 ml of Murashige-Skoog+ 3% sucrose, (III) sand, and (IV) sand + 3% sucrose. For treatments (I) and (II) the seeds were sown in 10 × 10 cm vessels then covered with Parafilm and aluminum foil.While treatments (III) and (IV) were sown in 20 ×40×10 cm plastic pots between two layers of sand, and keep themmoist during stratification. Then they were incubated at 4°C (cold stratification) for 45, 60 and 90 days. After each stratification period seeds were removed and washed with distilled water. In each replicate from each treatment and for each genotype 10 seeds were put on moistened filter paper in Petri dish (with 4 replicates), covered with aluminum foil, and incubated at 24℃ for ten days with observing their moist and score thegermination daily. The seeds were considered germinated when 5mm root penetrated seed coat.After 10 days of incubation the germination percentage was calculated for each treatment. Mean time for germination was calculated according to Daskalyuk(2002) using the formula:

$$T = (\sum_{i=1}^{L} \text{ni ti}) / \sum_{i=1}^{L} ni$$

where: L: germination period (10 days).
n_i: number of germinated seeds on the $_i$th day.
t_i: number of days.
The variance was analyzed by two way ANOVA, and LSD test (significance level 1%)was calculated to compare means using the statistical program SPSS17.

Results and Discussion

Germination percentage

The results showed that the stratification period of 45 days was not sufficient to germinate the seeds of studied apple rootstock genotypes in all studied mediums (Table, 1). However, seeds of B rootstockdid not germinate in mediums I (Murashige-Skoog) and II (Murashige-Skoog + 3% sucrose), while the highest germination percentage after 45 days stratification among studied genotypes was 35% in seeds of 'Golden Delicious' varietyin medium I. This result is in agreement with literature findings that the ability of apple seeds to germinate is tightly related to stratification period (Daskalyuk, 2002; Lewak, 2011).In genotype HS seedsgermination percentage in mediums I and IIafter 60 and 90 days of stratification, in addition to medium III (sand) after 60 days were insignificantly different (Table 1). The highest percentage was 87.5% after 60 days in medium II, and the same percentage was after 90 days in medium I. This results indicated that the addition of sucroseto Murashige-Skoog medium fasten the germination of seeds after 60 days' stratification. This is due to the necessity to energy and metabolites which sucrose provided to the embryo to start germination (Daskalyuk, 2002). On the other hand, in medium IV (sand + 3% sucrose) the germination percentage was lower in comparison with other mediums (Table 1).In B rootstock the results showed that medium IV (sand +3% sucrose)played an important role in shorten stratification period, which obtained high germination percentage (85%) after 60 days' stratification. This was insignificant with germination percentage of medium I and II after 90 days' stratification (83.3% and 88.8% respectively). The highest germination percentage of 'Golden Delicious' (GD) seeds was 87.5% in the mediums I and IV after 60 and 90 days respectively. On the other hand, the mediums II and III obtained low germination percentage of 'Golden Delicious' seeds in contrast with the other two mediums (Table 1).The results showed that the differences in seed germination percentage among studied genotypes, mediums, and after 60 and 90 days of stratification were insignificant. As well, these results revealed that 60 days' stratification is enough to have high germination percentage in all studied genotypes, but each genotype has a favorable medium. These results are in agreement with result the obtained by Daskalyuk (2002), that almost all 'Golden Delicious' seeds germinated after 60 days' stratification.

Mean time for seed germination

Table (1) showed that the mean time for seed germination decreased with the increase of stratification period in all studied mediums and genotypes. The mean time for seed germination insignificantly differed in the genotypes HS and Bin studied mediums and stratification periods. The mean time for seed germination in HS genotype was 2.7 days in medium III after 90 days' stratification, while it was 7.8 days in medium I after 45 days stratification. As well, the mean time for seed germination in B genotype was 3.1 days in medium II after 90 days' stratification,and reached 7.6 days in medium IV after 45 days' stratification. However, in mediums I and II after 45 days' stratification there was no germination. On the other hand, the mean time for seed germination of 'Golden Delicious' showed significant differences among studied mediums and stratification periods. It was between 3.5 days in medium I after 90 days' stratification, and 9 days in medium II after 45 days' stratification (Table 1). These results illustrated clearly the relationship between the stratification period and the speed of seed germination. This is in agreement with the results obtained by Daskalyuk (2002), Lepse*et al*. (2011), and Suleiman and Omran (2011)that seeds germination percentage and time for germination of apple seeds correlated to stratification period.When we compared the germination percentage between genotypes on the same medium for

different periods, we found that each genotype showed differentbehavior than the other studied genotypes, especially 'Golden Delicious' variety, because the length of stratification period depends on species and cultivars, which was in agreement withLewandowski and Zurawicz (2009).

Table 1: Germination (G) percentage (%) and mean time (T) for germination (days) in each medium, stratification period and genotype.

Medium	Stratification period	Genotype					
		HS		B		GD	
		G (%)	T(days)	G (%)	T(days)	G (%)	T (days)
I (Murashige-Skoog)	45	22.5 c	7.8	0 h	-	35 d	6.6 b
	60	80 a	5.1	38.7 f	6.3	**87.5 a**	4.1de
	90	**87.5 a**	3	83.3 ab	3.9	69 b	3.5 e
II (Murashige-Skoog + 3% sucrose)	45	10 d	7.5	0 h	-	2.5 e	9 a
	60	**87.5 a**	5.1	50 e	7.1	62.5 b	5.9bcd
	90	82.5 a	3.7	**88.8 a**	3.1	*	-
III (sand)	45	30 c	7.2	2.5 h	7	30 d	5.1bcde
	60	80 a	3.9	75 c	6.3	51.3 c	6.5bc
	90	28.8 c	2.7	62.5 d	5.2	67.5 b	4.6cde
IV (sand + 3% sucrose)	45	7.5 d	7	12.5 g	7.6	10 e	5.9bcd
	60	50 b	5	**85 ab**	6	45 c	8.2a
	90	57.5 b	4.2	77.5 bc	5.3	**87.5 a**	4.1de
LSD 1%		9.4		7.7		9.6	1.9

*the treatment is lost.

Same letters (a,b,c ….) in each column indicated that the difference between mean values is insignificant.

Conclusion

The results showed that 60 days' stratification period was efficient to get high seed germination in all studied genotypes, in the mediums Murashige-Skoog + 3% sucrose for HS genotype, Murashige-Skoog for 'Golden Delicious' variety, and sand + 3% sucrose for B rootstock. On the other hand,90 days' stratification period was the better for shortened the time needed for germination. Hence, it is important for breedersand nurserymen which use seedling apple rootstocks to test the best medium and stratification period to improve their production.

Abstract

This study was conducted to determine the optimal planting time and the effect of humic substance in the Fondant *Hyacinthus* variety bulbs in Selcuklu district in Konya Province. We investigated the effects on flower quality and flowering period of applications: 1) I. planting time (November 7) (unfertilized), 2) II. planting time (November 28) (unfertilized), 3) III. planting time (December 19) (unfertilized), 4) I. planting time (November 7) (Tki-Humas), 5) II. planting time (November 28) (Tki-Humas), 6) III. planting time (December 19) (Tki-Humas). According to findings, the longest flower stems we had at the III. planting time with 12.02 cm (unfertilized) and III. planting time with 12.17 cm (Tki-Humas); the longest flower stalks (Tki-Humas) we had at I. planting time with 1.15 cm (Tki-Humas), at II. planting time with 1.16 cm (Tki-Humas), at III. planting time with 1.17 cm (Tki-Humas) and at III. planting time with 1.19 cm (unfertilized); the maximum number of flowers per stem with 37.00 number had II. planting time (Tki-Humas); the longest flower diameter with 6.98 cm had III. planting time (Tki-Humas); the longest leaf with 16.72 cm had I. planting time (Tki-Humas); the widest leaf with 3.33 cm had III. planting time (Tki-Humas); the opening of the first flowers began on March 26 in all applications; the duration of flowering is determined to be 22 days in all applications; the effect of the applications on the number of leaves was not statistically significant.

Keywords: *Fondant Variety (Hyacint), Planting Time, Humic Substance, Quality, Flowering Period.*

Introduction

Garden hyacinth (*Hyacinthus orientalis* L.) belong to the *Hyacinthaceae* family, *Hyacinthus* genus. Turkey is one of the world's richest countries in terms of the multitude of plant species. There are approximately 10.150 plant species in Turkey. About 3.000 of these plants are endemic. The plants growing in our country carry commercial value both in the country and abroad. The number of species collected from the nature and exported is 347 of them are bulbous tubers (Özhatay *et al*., 1997). In Turkey can be considered paradise geofit, dismantling the nature of more accelerated reduction and agreed on the complete ban would be a great benefit in the next 10 years. Sectors engaged in geofitler also emphasized that they should continue their production activities they have started in recent years, not to be dependent on nature. They have proven that geofitler can be produced easily within the framework of sustainability rules as long as the choice of the place, especially the Western Taurus, is benefited from the studies made (Karagüzel *et al*., 2011). Reducing the K + / Na + and Ca2 + / Na + ratios under salt stress of *Hyacinthus orientalis* L. leaves have been found to be a major contributor to the hyacinth salt tolerance (Köksal *et al*., 2014).

Onion plants have an important export potential with its different usage areas, and the need for these plants is increased by the increase of usage areas. Initially, the natural disasters meet the needs of these plants, but recent dismantling has failed to meet this need, and even extreme dismantling from nature has stressed that some of these endemic plants threaten their generation. Natural production methods could not fully meet the needs of these plants. Rapid propagation can be done by tissue culture methods and that an alternative production method

to natural production methods can be developed by using these methods. Thanks to the rapid propagation, tissue culture methods should be regarded as an alternative production method in order to protect the rich biodiversity of our country and that these works need to be supported by these works, in order to be able to respond to increasing needs and to prevent the generations of these plants from being destroyed (Karaoğlu, 2010). Considering the increase in number of onions, environmental length and environmental length, the study predicted that if the cultures were taken from geophytes, they would be able to obtain marketable quantities and quality, meet market demand for flower bulb exports, and have potential to become an alternative product (Özel and Erden, 2010).

Materials and methods

In this study, Fondant hyacinth variety was used as research material (Figure 1). The variety, Asia Lale Construction Agriculture, Animal Husbandry Trading Timited Company. It is operating in Konya. Onions are Health Certified, ISO-9001 Quality Standards and TSE 2547 Number Flower Bulbs Standards. The effects of three different planting times and humic substance (Tki-Humas) on the flower quality and flowering period were tried to be determined in the Fondant hyacinth variety in Selçuklu district in Konya province. Experimental design; 1) I. planting time (November 7) (unfertilized), 2) II. planting time (November 28) (unfertilized), 3) III. planting time (December 19) (unfertilized), 4) I. planting time (November 7) (Tki-Humas), 5) II. planting time (November 28) (Tki-Humas), 6) III. planting time (December 19) (Tki-Humas). The first planting of the hyacinth was on November 7th. Other plantings were made with 20 day intervals. In each planting, 180 pieces and 3 replications total 540 pieces of onion were used. The experiment was set up on openly field. The parcel was set at 60 x 75 cm, between rows and 15 cm x 15 cm at the planting distance. All bulbs were planted at an average depth of 12 cm.

Figure 1. Fondant hyacinth variety

Composition of tki-humas

Tki-humas; leonardite and a liquid natural organic soil conditioner produced from low quality lignite containing 12% humic and fulvic acid (Gezgin, 2013). Total Organic Matter: 5%, Humic Acid + Fulvic Acid: 12%, Water Soluble Potassium Oxide (K_2O- 3%), PH: 11-13.

Application of tki-humas

The hyacinth bulbs were sprayed onto the soil surface at a rate of 20 l/da just before planting, ensuring homogeneous mixing of the humic material with 20 cm soil depth. The application was made at cool time near the evening hours.

Examined parameters

Flower stem length (cm): The flowering of 10 plants until the end of flowering with the deviation of flowers begins to bloom from the bottom of the flower deviations. The arithmetic averages of the figures obtained are taken into account.

Flower stalk thickness (cm): The flower stem thicknesses of 10 plants selected randomly for each replicate were measured using digital calipers. The arithmetic averages of the figures obtained are taken into account.

Number of flowers per stem: The number of flowers per stem was determined by counting method for 10 randomly selected plants for each replicate. The arithmetic averages of the figures obtained are taken into account.

Flower diameter (cm): The diameters of 10 flowers collected randomly according to the varieties from the parcels; the distance between the two opposite points of the opposite points was determined with the help of the ruler in the period when the flowers fully opened. The arithmetic averages of the figures obtained are taken into account.

Leaf number (number/plant): During the time until the end of flowering, the leaves of 10 plants selected randomly per parcel were counted and averages were calculated. The arithmetic averages of the figures obtained are taken into account.

Leaf length (cm): The leaves of 10 plants randomly selected per plot during the time until the end of flowering were measured with the aid of a length ruler at the distance from the leaf exit point on the neck portion of the onion to the extreme point. The arithmetic averages of the figures obtained are taken into account.

Leaf width (cm): The diameter of the best growing leaves of 10 plants randomly selected per plot was measured with the aid of a ruler until the end of flowering. Measurements were made with reference to the middle, which is the largest of the leaf. The arithmetic averages of the figures obtained are taken into account.

Determination of flowering time: All the hyacinth plants in the control group and the fertilizer application were taken as the flowering time of the first flowers opened.

Determination of flower life: The number of days between the appearance of the first flower and the fading of the flower was taken into account.

Evaluation of data: Results obtained were analyzed in JMP (version 7.0, SAS Institute, Cary, NC, USA) statistical program.

Results and discussion

The measurements and findings obtained in the fondant hyacinth variety were interpreted as 3 repetition averages (Table 1).

a, f: The difference between averages with different lowercase letters in the same column is important (P<0.05), N.S.: No significant, I. Planting Time (07 November), II. Planting Time (28 November), III. Planting Time (19 December).

Effect on flower stem length of applications

The longest flower stems had III. planting time with 12.02 cm (unfertilized) and III. planting time with 12.17 cm (Tki-Humas); The shortest flower stem had II. planting time with 10.73 cm (unfertilized) and I. planting time with 11.03 cm (unfertilized) was determined (Table 1).

Effect on flower stalk thickness of applications

The longest flower stalks thickness had I. planting time with 1.15 cm (Tki-Humas), II. planting time with 1.16 cm (Tki-Humas), III. planting time with 1.17 cm (Tki-Humas) and III. planting time with 1.19 cm (unfertilized); The shortest flower stalk thickness had I. planting time with 0.96 cm (unfertilized) (Table 1).

Effect on number of flower per stem of applications

The maximum number of flowers per stem with 37.00 number had II. planting time (Tki-Humas); The least number of flower per stem had I. planting time with 22.00 number (unfertilized) (Table 1).

Effect on flower diameter of applications

The longest flower diameter with 6.98 cm had III. planting time (Tki-Humas); The shortest flower diameter had I. planting time with 5.97 cm (unfertilized) (Table 1).

Effect on leaf number of applications

The effect of the applications on the number of leaves was not statistically significant (Table 1).

Effect on leaf length of applications

The longest leaf with 16.72 cm had I. planting time (Tki-Humas); The shortest leaf had II. planting time with 15.11 cm (unfertilized) (Table 1).

Effect on leaf width of applications

The widest leaf with 3.33 cm had III. planting time (Tki-Humas); The shortest leaf width has II. planting time with 3.03 cm (unfertilized) (Table 1).

Effect on flowering time

The opening of the first flowers began on March 26 in all applications (Table 1).

Effect on flower life

The duration of flowering was 22 days in all applications.

Conclusion

The longest flower stems had III. planting time with 12.02 cm (unfertilized) and III. planting time with 12.17 cm (Tki-Humas); The longest flower stalks thickness had I. planting time with 1.15 cm (Tki-Humas), II. planting time with 1.16 cm (Tki-Humas), III. planting time with 1.17 cm (Tki-Humas) and III. planting time with 1.19 cm (unfertilized); The maximum number of flowers per stem with 37.00 number had II. planting time (Tki-Humas); The longest flower diameter with 6.98 cm had III. planting time (Tki-Humas); The longest leaf with 16.72 cm had I. planting time (Tki-Humas); The widest leaf with 3.33 cm had III. planting time (Tki-Humas); The opening of the first flowers began on March 26 in all applications. The duration of flowering was 22 days (March 26–April 17) in all applications. As a result, number of flowers per stem with II. planting time (November 28) (Tki-Humas) and flower diameter with III. planting time (December 19) (Tki-Humas) can be increase in Fondant hyacinth variety.

Acknowledgement

This work has been compiled from a part of İrfan Kalkan's Master Thesis. In addition, this thesis was supported by project number 17201056 by Selçuk University Scientific Research Projects (BAP) Office Directorate. We would like to thank the project office manager and employees for their contribution.

Abstract

This study was carried out to determine yield and the factors affecting yield of some sesame varieties and lines in the experimental field of Siirt University Faculty of Agriculture at the sesame growing seasons of 2016 and 2017 as second crops. In the experiment, ten different sesame genotypes were used as material, that consisting of three registered sesame varities (Arslanbey, Hatipoğlu, Boydak) and seven different lines. The study was designed with 3 replications according to randomized block trial design. According to the results obtained for two years study, the plant length is 104.13-152.87 cm, the first branch height is 2.67-11.87 cm, the number of plant branches is 1.87-10.33, the number of capsules per plant is 90. 93-200.33 units, 1000 grain weights were found to be between 3.25 and 4.83 g and the hectare yield varied between 479.29-1579.88 kg. The highest grain yield was obtained from the Arslanbey variety with 1579.88 kg / ha in 2016 and from line-8 with 1502.41 kg in 2017. The lowest grain yield was obtained from line-7 with 479.29 kg in the first year and from line-3 with 68.69 kg in the second. It has been determined that genotypes are significantly different from one another in terms of yield and other characteristics, and it turns out that these varieties show different responses.

Keywords: *Sesame, Genotype, Yield, Factors affecting yield*

Introduction

Sesame (*Sesamum indicum* L.) was cultivated and domesticated on the Indian subcontinent during Harrapan and Anatolian eras (Bedigian and Van der Maesen, 2003). This is evidenced by the presence of archaeological remnants of the crop dating back to 5500 BC in the Harappa Valley in the Indian subcontinent (Weiss, 2000; Ashri, 2007). The Assyrian tablets depict how the gods ate bread and drank sesame wine together prior to battling and restore order to the universe. Sesame was a major oilseed crop in the ancient world due to its easiness of extraction, great stability, and resistance to drought. It is also known as benniseed, gingelly, simsim, ajonjoli, sesamo and til. The genus *Sesamum* is a member of Pedaliaceae family, which contains 16 genera and 60 species. The number of sesame species is not clear; however, about 40 species have been described, and 36 are mentioned in the Index Kewensis. Many occur in Africa (18 exclusively), 8 occur in the Indian – Ceylon region (5 exclusively). Almost all of the wild species are prevalent in Africa. *Sesamum indicum*, as well as *S. capense* Burm. (*S. alatum* Thonn.) and *S. Schenkii* Aschers, has a somatic number 2n = 26. For *S. laciniatumthis* is 2n = 28. For *S. angolens* and *S. prostratum* it is 2n = 32. For *S. occidenale* and *S. radiatum* Schm & Thonn. it is 2n = 64. *Ceratotheca sesamoides*, related to *Sesamum*, has 2n = 32. Only *Sesamum indicum* is cultivated; however, a few other species: *S. angustifolium, S. calycinum,* ssp. *Baumii, S. malabaricum,* and *S. radiatum* are harvested and eaten occasionally, particularly during famine or food shortage (Ashri, 2007).

Oil extracted from sesame is honoured as a rich food because of its high nutritive quality and stability (Nayar et al., 2002). It has many uses and it is markedly different from other vegetable oils due to its high nutritional and therapeutic values. Potential health benefits of

sesame include anti oxidative, anticancer, anti-hypersensitive and anti-immunoregulatory actions (Reshma et al., 2010). The seeds are used for the production of oil, paste, salads and in various food formulations. From the chemical composition of sesame, it is known that the seeds contain 50-60% oil, 18-25% protein, 13.5% carbohydrate and 5% ash (Elleuch et al., 2007). The noteworthy stability to oxidation can be attributed to its endogenous anti-oxidant lignans along with tocopherols (Reshma et al., 2010). Sesamin (0.4-1.1%), sesamolin (0.3-0.6%) and traces of sesamol contribute to the unique properties of sesame oil (Shahidi et al., 1997). In the eastern parts of the world, sesame has long been considered as a 'health food' that provides high energy and prevents ageing (Yoshida et al., 2007). The oil is rich in unsaturated fatty acids (85%) and has a mild taste. It is said to be plant breeder's dream crop because of its great genetic diversity (Banerjee et al., 2009). Sesame is a rich source of calcium (approx 1%) and phosphorous (approx 0.7%) (Nayar et al., 2002). Sesame contains ample amounts of oleic (43%), linoleic (35%), palmitic (11%) and stearic acid (7%) which together comprise 96% of the total fatty acids (Saydut et al., 2008).

Sesame seeds are tiny, flat, oval with a nutty taste and delicate with almost invisible crunch. They vary in size from small to large and come in a host of different colours, depending upon the variety, including white, yellow, black, grey, brown and red. The seeds from northeast region of India are black; those from eastern region are brown to black and from south are predominantly red or reddish brown.

Taking into consideration the use of the existing oil shortage and sesame in different areas of our country, it is of great importance to increase the yield to be obtained from the unit area in sesame seeds. In fact sesame agriculture offers a very profitable production, with little input from the other side except labor input. If progress is made in the harvest mechanization of sesame, sesame agriculture in the Southeastern Anatolia region is thought to be more prevalent as a second crop in irrigated areas.

Material and Methods

This study was carried out to determinate of appropriate sesame genotype in the experimental field of Siirt University Faculty of Agriculture at the sesame growing seasons of 2016 and 2017 as second crops. In this study, it was aimed to investigate the possibilities of breeding of different sesame varieties foreseen under the conditions of Siirt Province. In the experiment, ten different sesame genotypes were used as material, that consisting of three registered sesame varities (Arslanbey, Hatipoğlu, Boydak) and seven different lines. The study was designed with 3 replications according to randomized block trial design. In the experiment, the distance between the rows was 70 cm and the distance from the rows was 15-20 cm.

Test site soil properties; Siirt University Kezer Campus Agricultural Faculty is the land of the field trial field trial, terraced, with an east-facing, flat and steeply sloping, alluvial construction, with deep profiled soil. According to the result of soil analysis at the depth of 0-30 cm before planting in the experimental area, the whole area of the study site was roughly textured (47,99% sand, 8,49%, 43,51% clay), little salty (463 mS / organic matter (1.02%), with respect to the amount of phosphorus that can be absorbed, and organic (organic matter) There is insufficient substance, sufficient capacity for potassium.

The experiment was carried out every two years after the harvest of the lentil as the second crop. 1 year; 15 June was planted in 2016, 2nd year; July 5, 2017 sowing was done. The trials were irrigated with drip irrigation system that was done 6 times in both growing season. Plants were harvested from middle two rows of 4 rows per plot treatment for **seed yield.** Harvest was done by hand. The harvesting and blending process began at the middle of October and finished towards the end of November.

The meteorological data were recorded from planting date to the harvest time in Table 1. Below are temperature and humidity tables for 2016 and 2017 of Siirt province (Anonymous 2018).

Results and Discussion

In the study; seed yields of sesame cultivars and lines, plant size, number of capsules per plant, number of side branches in the plant and 1000 seed weight were given in the table 2, According to the results obtained for two years study, the plant length is 104.13-152.87 cm, the first branch height is 2.67-11.87 cm, the number of plant branches is 1.87-10.33, the number of capsules per plant is 90. 93- 200.33 units, 1000 grain weights were found to be between 3.25 and 4.83 g and the hectare yield varied between 479.29-1579.88 kg, The highest grain yield was obtained from the Arslanbey variety with 1579.88 kg / ha in 2016 and from line-8 with 1502.41 kg in 2017, The lowest grain yield was obtained from line-7 with 479.29 kg in the first year and from line-3 with 68.69 kg in the second. It has been determined that genotypes are significantly different from one another in terms of yield and other characteristics, and it turns out that these varieties show different responses.

Conclusions

The study was carried out for 2 years. In terms of the factors affecting yield and yield in different sesame genotypes, different responses were seen in every two years. Such as, in 2016, it is seen that the production of Arslan bey is higher than the yield in 2017 (Table 2), but from Chart 1 it is seen that the sesame growing season of 2016 is warmer than the season of 2017. This can be expressed as the fact that the genotypes of different genotypes are different from each other and thus react differently to changing climatic conditions.

THE BUDDING SUCCESS IN LOQUAT (*ERIOBOTRYA JAPONICA* LINDL.) ON DIFFERENT QUINCE ROOTSTOCK

Atila Aytekin POLAT*

Mustafa Kemal University, Faculty of Agriculture, Department of Horticulture, Antakya, 31034 Hatay, Turkey

Abstract

The purpose of the work was to find out the success of budding of loquat on different Quince rootstocks and the effect of these rootstocks on the growth of the nursery plants. For this purpose, Hafif Çukurgöbek loquat cultivar was budded on Quince-A, Quince-C and BA-29 rootstocks with chip budding on 25 April (spring), and 21 October (dormant), 2016. The experiment was laid out in a split-plot experimental design with five replications and fifteen plants per replication. The percentage values were transformed by the angle transformation before submitting the data to the analysis of variance. The means were separated by Tukey's Honestly Significant Difference (HSD) method at p=0.01 and p=0.05. The average success rate of budding on Quince rootstocks was better in October (89.2%) than in April (79.3%). In the both budding periods, it was found that buddings on BA-29 (respectively, 85.5% and 93.1%) were more successful than the ones on Quince-A (respectively, 69.8% and 88.5%) and Quince-C (respectively 83.2% and 86.0%). However, the highest bud sprout rate (86.1 %) was taken from the buddings which were done on Quince-C rootstock in October. Budding performed in autumn gave the higher values (81.4%) of bud sprout rate than the budding done in spring (28.4 %). In the measurements made, the highest values of stock and scion diameter and annual shoot length of the nurseries were obtained from Quince-C rootstock. As result, preliminary data obtained from this research show those quince rootstocks as dwarf rootstock in intensive loquat cultivation can be used.

Keywords: *dwarf rootstock, loquat, budding success, high density.*

Introduction

In all Mediterranean countries, the rootstocks used are loquat seedlings; they are very well adapted to calcareous soils which are very abundant in the Mediterranean basin. Trails of quince trees (A, C, BA-29) have often been studied in some countries. This species allows smaller and more compact trees, a shorter juvenile period and bigger fruits, with high sugar content and nice color. However, quince trees are very sensitive to calcareous soils and they show graft union incompatibility with many varieties (Llácer *et al*. 2003). On the other hand, in China which is the main loquat producing country, the most used rootstock is loquat seedlings while in some areas, quince is used as dwarfing rootstock (Lin, 2007).

The use of loquat seedling rootstock usually results in a comparatively large tree with a high canopy. Cultivars grown on quince rootstock produce a dwarfed tree of early bearing character. The smaller tree has no effect on fruit size and gives adequate fruit production with the advantage of easier picking (Crane and Caldeira, 2006). Commonly, trees are grafted onto loquat seedlings, occasionally on *Eriobotrya deflexa*, and *Photinia serrulata*, and may be grafted onto dwarfing rootstocks of quince (*Cydonia oblonga* Mill.) and pyracantha (*Pyracantha* spp.).

At present, the rootstocks used are loquat seedlings in Turkey. However, the dwarfing rootstocks are very important in loquat culture. The utilization of the dwarfing rootstocks therefore higher yields, but also will have other advantages such as easier and more effective cultural applications (Polat and Kaska 1992a, 1992b). We suggest dwarfing rootstocks such as Quince-A and BA-29 for loquat production. This species allows growers to obtain smaller and

more compact trees. In some of our studies (Polat and Kaska, 1992a; Polat 1995), Quince-A rootstock had a 25% dwarfing effect compared to loquat seedlings. Polat and Calıskan (2007) recommended that nurseries should initiate grafting loquat onto quince rootstock. The purpose of the work was to find out the success of budding of loquat on different Quince rootstocks and the effect of these rootstocks on the growth of the nursery plants.

Material and Method

This research was carried out during two growing sessions 2016 and 2017 at experimental nursery of Department of Horticulture, Faculty of Agriculture, Hatay Mustafa Kemal University, Antakya, Hatay, Turkey. Hafif Çukurgöbek loquat cultivar was budded on Quince-A, Quince-C and BA-29 rootstocks with chip budding on 25 April (spring), and 21 October (dormant), 2016. The plants were irrigated by drip irrigation. The experiment was laid out in a split-plot experimental design with five replications and fifteen plants per replication. In the spring period, the percents of bud-take successes were recorded after two months of the budding operations, whereas the observations on bud sprout rates were determined after four months of the budding. Bud take and bud sprout rates were determined respectively, 22 February 2017 and 31 March 2017, in the dormant buddings. The annual shoot length, plant height and trunk diameter (5 cm below and above of bud union) of all nurseries were determined interval one month during the growth period. The percentage values were transformed by the angle transformation before submitting the data to the analysis of variance. The means were separated by Tukey's Honestly Significant Difference (HSD) method at p = 0.01 and p=0.05.

Result and Discussion

Budding Success

The success rates of budding made in different periods are presented in Table 1. In all rootstocks, the budding success rates were found higher in fall (dormant) buddings than in spring ones. The average budding success rate was higher in October (89.2%) than in April (79.3%). The differences between the budding periods were statistically significant at $p<0.01$. In the both budding periods, it was found that buddings on BA-29 (respectively, 85.5% and 93.1%) were more successful than the ones on Quince-A (respectively, 69.5% and 88.4%) and Quince-C (respectively 83.2% and 86.0%). The differences between the rootstocks were statistically significant at $p<0.01$.

Table 1. The success rates of budding made in different times

Rootstocks	Time of budding		Average (%)
	24 Ap, 2016	21 Oct. 2016	
Quince-A	69.51 d$^{(y)}$	88.45 ab	78.98 B$^{(x)}$
Quince-C	83.24 c	86.00 bc	84.62 AB
BA- 29	85.22 bc	93.13 a	89.17 A
Average (%)	79.32 B$^{(x)}$	89.19 A	

$^{(x)}$Means followed by different capital letters are for rootstocks and budding dates and indicate significant difference by Tukey's test at 0.01.

$^{(y)}$Means followed by different lowercase letters are for rootstock x budding dates interaction and indicate significant difference by Tukey's test at 0.01.

However, the highest bud sprout rate (86.1 %) was taken from the buddings which were done on Quince-C rootstock in October, 2016. The bud sprout rates were found higher in autumn (81.4%) buddings than in spring (28.4 %) ones (Table 2).

Table 2. The bud sprout rates of budding made in different times

Rootstocks	Time of budding		Average (%)
	24 Apr.2016	21 Oct. 2016	
Quince-A	31.43 c[(y)]	76.99 b	54.21 AB[(x)]
Quince-C	30.33 cd	86.11 a	58.22 A
BA- 29	23.31 d	81.05 ab	52.18 B
Average (%)	28.36 B	81.38 A	

[(x)]Means followed by different capital letters are for rootstocks and budding dates and indicate significant difference by Tukey's test at 0.01.
[(y)]Means followed by different lowercase letters are for rootstock x budding dates interaction and indicate significant difference by Tukey's test at 0.01.

Rootstock × budding period interaction was statistically significant at p=0.01 indicating that rootstocks are affected differently with budding time. In both time of budding, BA-29 had the highest bud-take rates while the lowest bud-take rates was observed in Quince-A on April, 2016, Quince C on Oct., 2016. In previous studies with Quince-A (Polat and Kaşka, 1992a), indicate 54.8% budding success in spring budding and 36.0% in dormant buddings made in fall. The budding made in April gave more successful those than in May. In loquat budded onto Quince-C rootstock, 56.7% budding success has been achieved (Polat and Kaşka, 1992b) and a budding success rate of 66.5% was achieve by Yinanç (2000) onto Quince-A.

Vegetative trait

The annual length of shoot, height of plant and scion-stock trunk diameter of nurseries are presented in Table 3. In the measurements made, the highest values of stock and scion diameter, plant height and annual shoot length of the nurseries were obtained from Quince-C rootstock and this was followed by BA-29. The lowest values were observed on Quince –A rootstock for all parameter. The differences between the rootstocks were found statistically significant at $p<0.01$ for the scion diameter while found statistically significant at $p<0.05$ for the stock diameter, plant height and annual shoot length.

Table 3**.** The effects of quince rootstocks on the characteristics vegetative growth of Hafif Çukurgöbek cultivar.

Rootstock	Scion diameter (mm)	Stock diameter (mm)	Plant height (cm)	Lenght of shoot (cm)
Quince-A	13.73 b[(x)]	17.73 b	53.96 b	30.90 b
Quince-C	20.57 a	23.94 a	69.66 a	44.88 a
BA- 29	17.31 ab	21.63 ab	64.46 ab	38.76 ab
HSD	p<0.01	p<0.05	p<0.05	p<0.05

[(x)]Means within a column followed by different letter are significantly at the 5% level by Tukey's HSD test.

Conclusion

Budding success depends on a lot of factor in fruit trees. Ecology, rootstock and variety features, budding or grafting techniques, and care after budding or grafting can be counted among these factors. When the results compared to the other research, it shows that our results

are quite successful. The average success rate of budding on Quince rootstocks was better in October (89.2%) than in April (79.3%). In the both budding periods, it was found that buddings on BA-29 were more successful than the ones on Quince-A and Quince-C. However, the highest bud sprout rate (86.1 %) was taken from the buddings which were done on Quince-C rootstock in October. In the measurements made, the highest values of stock and scion diameter and annual shoot length of the nurseries were obtained from Quince-C rootstock. As result, preliminary data obtained from this research have shown that can use of quince rootstocks as dwarf rootstock in intensive loquat cultivation.

Abstract

In the research, it was aimed to determine the effects of different quince rootstocks on phenological stages and inflorescence properties besides to the success of obtaining dwarf loquat nursery, which was a requirement of intensive loquat cultivation. For this purpose, one year old nursery of Hafif Çukurgöbek loquat cultivar budded on BA-29, Quince-A and Quince-C quince rootstocks was used. The experimental plants were planted at high density with planting spaces of 1.0 m x 0.5 m in January 2017. The plants were irrigated by drip irrigation since their transplantation. The experiment was arranged according to a completely randomized designed with 5 replications and 6 plants were used in each replicate. In the study, effects of the rootstocks on the flowering periods, the inflorescence characteristics, flowering and fruit set rates of the cultivar were evaluated. In terms of the number of flower buds in the inflorescence (bud/per cluster), plants with Quince-A rootstock (114.91) were given higher values than the BA-29 (106.13) and Quince-C (104.06) rootstocks. However, the highest blossoming rate was observed on BA-29 (99.22%), followed by Quince-C (87.36%). The lowest blossoming rate was measured in plants with Quince-A rootstock (86.27%). Plants with BA-29 rootstock reached full bloom 7-15 days before the other two rootstocks. The fruit set ratios were observed similar in plants with Quince-A and Quince-C rootstocks (14.68 %, 14.11, respectively) whereas the lowest fruit set ratio was observed in and BA-29 rootstock (10.29%).

Key words: *BA-29, Quince-A, Quince-C, rootstrock, phenological properties.*

Introduction

Loquat seedlings, quince, and hawthorn can be used as rootstocks for loquat (Polat, 1995). Loquat seedlings are preferred over quince or pyracantha rootstocks under most conditions. Quince and pyracantha may cause extreme dwarfing–to less than 8 ft (2.5 in). Quince rootstock tolerates heavier and wetter soils than loquat but is apt to put out numerous suckers (Crane and Caldeira, 2006).

Loquat is a large tree which restricts the number of trees that can be planted per unit area and makes it necessary to harvest fruit with ladders. Furthermore many of the large trees show considerable juvenility, delaying the onset of commercial harvest. The use of dwarfing rootstocks using quince (*Cydonia oblonga*) is one method to reduce tree size, facilitate harvest, and increase early yield, but compatibility of loquat and quince is low(Janick, 2011).

The use of dwarfing rootstocks in loquat production reduces tree size making it possible to plant more trees per unit area and thereby increase early yield (Polat et al., 2004), facilitate harvest, and reduce costs (Polat et al., 2003). Quince rootstocks slow scion growth reducing tree size by 20 to 25% as compared to loquat seedlings, increase earliness, and increase fruit quality and size (Demir, 1987; Polat and Kaşka, 1992a, b; Polat, 1995).

At present, the rootstocks used are loquat seedlings in Turkey. However, the dwarfing clonal rootstocks are very important in loquat culture. The utilization of the dwarfing therefore higher yields, but also will have other advantages such as easier and more effective cultural applications (Polat and Kaska, 1992c, 1992d, 1992e). We suggest dwarfing, clonal rootstocks such as Quince-A and BA-29 for loquat production. This species allows growers to obtain

smaller and more compact trees. In some of our studies (Polat and Kaska, 1992c; Polat, 1995), Quince-A rootstock had a 25% dwarfing effect compared to loquat seedlings. Polat and Calıskan (2007) recommended that nurseries should initiate grafting loquat onto quince rootstock.

In the research, it was aimed to determine the effects of different quince rootstocks on phenological stages, and inflorescence properties besides to the success of obtaining dwarf loquat nursery, which is a requirement of intensive loquat cultivation.

Material and Method

This research was carried out during two growing sessions 2016-2017 and 2017-2018 at experimental nursery of Department of Horticulture, Faculty of Agriculture, Hatay Mustafa Kemal University, Antakya, Hatay, Turkey. In the study, one year old nursery of Hafif Çukurgöbek loquat cultivar budded on BA-29, Quince-A and Quince-C quince rootstocks was used. The experimental plants were planted at high density with planting spaces of 1.0 m x 0.5 m in January 2017. The plants were irrigated by drip irrigation since their transplantation. The experiment was arranged according to a completely randomized designed with 5 replications and 6 plants were used in each replicate. In the study, effects of the rootstocks on the flowering periods, the inflorescence characteristics, flowering and fruit set rates of the cultivar were evaluated. Flower buds were observed from full rest until fruit set. Data were taken on date of first blossoming, full bloom, end of blossoming and harvest time. We considered the beginning of flowering as the date when 5% of the flowers were open; 70% as full bloom and 90% petal drop as the end of blossoming (Durgac et al., 2006). To determine the flowering periods and the fruit set rate of the cultivar according to rootstocks, a branch was selected randomly from the four sides of the canopy and they were tagged accordingly. All flower buds were counted at the pre-blossom phase at each of these selected branches to carry out phenological observations. The flowers of each tagged branch were counted and % blossom rate was calculated by taking the proportion of the flower amount to bud amount during the observations made between the phase when blossoming starts and ends. 10 days after the end of blossoming, the number of initial fruits was found and by dividing this number by flower amount, % initial fruit set was determined. The fruit set was determined one month after the initial fruit set. Percentage final fruit set was determined by taking the proportion of the amount of fruit during the maturing period to the amount of flowers. The percentage values were transformed by the angle transformation before submitting the data to the analysis of variance. The means were separated by Tukey's Honestly Significant Difference (HSD) method at $p = 0.01$.

Result and Discussion

Cluster Characteristics and Fruit Set

The effects of the Quince rootstocks used in the experiment on blossoming rate and inflorescence characteristics of the Hafif Çukurgöbek cultivar are given in Table 1.

As shown in Table 1, in all three rootstocks, the number of cluster per branch of the Hafif Çukurgöbek cultivar was the same and did not show any difference according to the rootstocks. Although there is no significant difference in terms of the average number of secondary axis on the main panicle axis, the number of secondary axis on Quince-A was found to be somewhat higher. On the other hand, in terms of the number of flower buds in the inflorescence (bud/per cluster), plants with Quince-A rootstock (114.91) were given higher values than the Quince-C (104.06) and BA-29 (106.13) rootstocks (Table 1).

Table 1**.** The effects of some Quince rootstocks on blossoming and fruit set rates and inflorescence characteristics of the Hafif Çukurgöbek cultivar.

Rootstocks	No. of secondary axis per main panicle axis	No.of flower bud per cluster	No.of opened flower per cluster	Blossoming Rate (%)	Inital fruit set (%)	Fruit set (%)	Final fruit set (%)
Quince-A	12.74 a[(x)]	114.91 a	98.57 ab	86.27 b	22.60 a	14.68 a	1.80 c
Quince-C	12.57 a	104.06 b	89.55 b	87.36 b	20.34 a	14.11 a	6.59 a
BA-29	12.58 a	106.13 b	105.23 a	99.22 a	14.49 b	10.29 b	4.97 b
Significance	NS[(y)]	**	**	**	**	**	**

[(x)]Means within a column followed by different letter are significantly at the 1% level by Tukey's HSD test.
[(y)]Not significance

In terms of the number of flowers opened in the cluster, it was determined that the Hafif Çukurgöbek/BA-29 combination (105.23) bloomed higher than the Hafif Çukurgöbek/Quince-A(98.57) and Quince-C(89.55) combinations. Blossoming percentages were significantly affected by rootstocks. The highest blossoming rate was observed on BA-29 (99.22%), followed by Quince-C (87.36%). The lowest blossoming rate was measured in plants with Quince-A rootstock (86.27%). Initial fruit set rates of the rootstocks showed significant differences. The highest initial fruit set rate was in plants with Quince-A rootstock (22.60 %) and this was followed by Quince-C(20.34 %) and BA-29(14.49) rootstocks. The highest fruit set rate was observed on Quince-C (6.59%), followed by BA-29 (4.97 %). The lowest fruit set rate was measured in plants with Quince-A rootstock (1.80 %). The differences between the rootstocks for all these parameters were statistically significant at $p<0.01$ (Table 1).

We did not have a chance to compare our findings because we did not find a similar study in the literature for quince rootstocks. There are some studies on flowering and fruit set rates of different loquat cultivars. Polat (2007) observed that fruit set rates for loquats depend upon different genotypes, years, and environmental conditions. Our initial fruit set rates (14.49%–22.60%) are higher than those of Erdoğdu (1987) who tested 30 loquat cultivars under Adana conditions. The 5.0% fruit set rate which was found by Ateyyeh and Qrunfeh (1998) for 'Tanaka' was lower than our range. However, our results were similar those by Demir (1989) who studied the six cultivars with the range of 16.4–17.4% under Antalya (Turkey) conditions. The finding of Mann and Sagar (1987) of 15% is lower than our finding. It is obvious that fruit set rates for loquats depend upon different genotypes, and canopy facing side.

Phenological Data

The results related to the effects of the Quince rootstocks used in the experiment on the phenological stage of the Hafif Çukurgöbek cultivar are given in Table 2.

Flowering period of the Hafif Çukurgöbek/Quince rootstock combination were completed between 15 Dec. and 08 Feb. (Table 2). The first flowering was observed on the plants with BA-29 rootstock, plants with Quince-C rootstock began flowering later. Plants with BA-29 rootstock reached full bloom 7-15 days before the other two rootstocks. In terms of the other phenological phases, BA-29 rootstock was found earlier than the Quince-A and Quince-C rootstocks. The earliest fruit ripening was observed on plants with BA-29 rootstock (Table 2).

Table 2**.** The effects of the Quince rootstocks on the phenological stage of the Hafif Çukurgöbek cultivar

Rootstocks	The phenological properties					
	Bud swelling	Beginning of blossoming	Full bloom	End of blossoming	Fruit set	Maturity period
Quince-A	01.12.2017	28.12.2017	30.01.2018	05.02.2018	17.02.2018	16.05.2018
Quince-C	01.12.2017	30.12.2017	23.01.2018	08.02.2018	24.02.2018	16.05.2018
BA-29	29.11.2017	15.12.2017	15.01.2018	02.02.2018	15.02.2018	9.05.2018

Conclusion

As result, preliminary data obtained from this research show those quince rootstocks as dwarf rootstock in intensive loquat cultivation can be used. In terms of the all phenological phases, BA-29 rootstock was found earlier than the Quince-A and Quince-C rootstocks. The earliest fruit ripening was observed on plants with BA-29 rootstock.

Abstract

The advent of next-generation sequencing technologies and newly developed bioinformatics tools have provided us complete sequence information of organisms. Plant microRNAs (miRNAs), small non-coding RNAs about 21-24 nucleotides, and their regulatory roles in biological processes have been uncovered since the identification of the first miRNA. MicroRNA biogenesis and modes of actions have also been elucidated in previous studies.

In the presented study, we identified putative microRNAs from *Actinidia chinensis*, *Arabidopsis thaliana*, *Solanum lycopersicum*, *Solanum tuberosum* and *Vitis vinifera* to compare their miRNA repertoire. According to the results, the highest synteny was found between *V.vinifera-A.chinensis* and the least synteny was found between *A.thaliana-A.chinensis*. The highest number of putative miRNAs were identified from *A.thaliana* whereas the least amount of putative miRNAs were identified from *V.vinifera*. This may be depended on the size of the genomes. We also analyzed the targets of putatively identified miRNAs for each organism. Expectedly, the target pathways of the predicted putative miRNAs were similar between the closest organisms. Expressed miRNA families and copy number of miRNA genes were compared between all organisms. In *A.thaliana*, the number of expressed putative miRNAs are more than the other organisms. For all the organisms, different miRNA families had the high copy number of genes. Therefore, highly represented miRNA families on each genome may have specific functional roles. The findings in this study will help the research community to identify the roles of miRNA players on critical biological pathways.

Keywords: MicroRNAs*, Actinidia chinensis, Solanum tuberosum, Solanum lycopersicum, Vitis vinifera*

Introduction

Increasing world population, the drastic climate changes, the threat of biotic stress and abiotic stress factors on the plants and the scarcity of arable lands have created a big concern about the future sufficiency of food demands. To prevent this unwanted scenario in the next centuries, some new agricultural technologies should have been developed to ensure food security (Liu and Chen, 2010; Akpinar et al., 2012; Avsar, 2011). Recent studies show that revolutionary advances in next-generation sequencing techniques became popular in plant biology area. The advent of this new technologies has increased our knowledge from genomics to plant breeding and evolutionary studies. An increasing number of sequenced plant genomes will provide us the greater understanding of their genome, growth and developmental mechanism and evolutionary processes (Egan et al., 2012).

Non-coding RNAs or ncRNAs, such as transfer RNA (tRNA), ribosomal RNA (rRNA) and small nuclear RNA (snRNA) have been identified for a long time ago. Among ncRNAs, microRNAs (miRNAs) and small interfering RNA (siRNA) have gained more attention since they have been found as essential regulators of gene expression (Choudhuri, 2009). MicroRNAs have short lengths about 21-24 nucleotides emerged from their longer precursor sequences that are variable sizes between the plant species contrary to the animal

counterparts. After the discovery of plant miRNAs and their great regulatory roles in the cell, both computational and experimental strategies have been studied for identification of the related genes and microRNAs' targets. Experimental methods are based on direct cloning and genetic screening whereas computational methods are dependent on new generation sequencing technologies because this powerful technology is time-saving and cost-efficient. With the help of the bioinformatics and computational tools, miRNA studies have also been increased enormously for plant genomes. (Zhang and Wang, 2015; Avsar and Aliabadi, 2017a; Avsar and Aliabadi, 2017b; Avsar and Aliabadi, 2018).

The kiwifruit or Chinese gooseberry is the edible berry member in the Actinidia genus and recent genomic studies reveals that the kiwifruit species often have polyploidy structure with a chromosome number as x=29 results from hexaploidization and two more recent whole genome duplication events (McNeilage and Considine, 1989; Huang et al., 2013) and it completes the divergence from Solanaceae species such as tomato and potato. These duplication events have provided neo-functionalization of important genes including in vitamin C, flavonoid, and carotenoid metabolic activities. It also has one of the well-known fleshy fruit since it is an excellent source of several vitamins, minerals, dietary fibers and other related health benefit dietary nutrients (Skinner et al., 2011). In addition to this, recent studies show that the consumption of kiwifruit has positive effects on cardiovascular health through antioxidant activity and by promoting gut microflora. It has also found that the kiwifruit support immune system either by up-regulating some defense-related genes or activating 'DNA-repair' mechanism in the cells (Skinner et al., 2011).

Taken together, we predicted some putative miRNAs in silico between the kiwifruit *A. chinensis* and its close relatives by using genomic sequence data and computational tools to gain a better understanding of their relations and to provide a valuable resource for the evolutionary processes in the Asterid lineage. We also showed that clustering of miRNAs repertoire between chosen organisms does not show the same pattern as the relationship between their whole genome.

Material and Methods

Reference miRNAs and Datasets: miRBase corresponds to 4,802 unique mature miRNA sequences, and these mature miRNAs were used as a query in homology-based in silico miRNA identification. For *A.chinensis*, genome sequence was retrieved from the website. *A.thaliana*, S. lycopersicum, *S.tuberosum* and *V.vinifera* masked Ensemble Plants website provided genomic sequences.

In silico miRNA Identification based on Sequence Homology and Secondary Structure Conservation: A two-step strategy was adopted based on the preliminary selection of database sequences with homology to a previously known plant mature miRNA and their subsequent retention assessing the consistency of their secondary structure with pre-established pre-miRNA features (Zhang et al., 2006). The prediction was employed using two previously developed, in-house Perl scripts: SUmirFind and SUmirFold, described in detail in the publications. In the first step of homology-based miRNA prediction, SUmirFind script, which utilizes BLAST+ stand-alone toolkit, version 2.2.31 (Camacho et al., 2009) was used for detection of database sequences with homology (mismatch cutoff parameter set to <=3) to previously known plant mature miRNAs (Zhang et al., 2006).In the second step, SUmirFold, a script that generates secondary structures through UNAFold version 3.8 was used with parameters optimized to include all possible stem-loops generated for each miRNA query. SUmirFold output was further processed to eliminate redundant hits, resulting from cases where identical miRNAs were predicted from two similar query mature miRNA sequences. Moreover, hairpins with multi-branched loops, with inappropriate DICER cut sites at the ends of the miRNA-miRNA* duplex, or with mature miRNA sequence portions at the head of the

pre-miRNA stem-loop were also manually removed. This process was done for all genomic datasets of plant species.

Clustering of plant species based on the variety of their cumulative miRNAs: Mature miRNA sequences from each plant species were separately listed and the binary matrix showing cumulative miRNA datasets in all five plant species was formed. For hierarchical clustering, euclidian distance based centroid clustering was adopted. Distance matrix construction, clustering, and dendrogram generation were performed in the MINITAB program.

Target annotation of predicted miRNAs: Mature sequences were collected from each species and duplicates were removed. By using an online web tool, psRNA, an analysis was performed, and hit sequences were retrieved. These retrieved sequences were used as input data for the Blast2Go online web tool (Conesa and Götz, 2009). Target annotation charts were created for all plant species. Experimentally validated targets of predicted putative miRNAs were also detected in miRBase (Kozamara and Jones, 2013).

The copy number of miRNA genes and expression analysis of predicted miRNAs: Repeated same miRNAs that resulted from the similar query miRNA stem-loop sequences were eliminated to avoid over-representation. The EST-database was formed separately as a specific to each plant species, and the restricted criteria were used for the analysis as the only miRNA families who had hits above the threshold as 98% identity, and 99% query coverage were retrieved.

Results and Discussions

Putative predicted miRNAs and their distribution across plant species: We identified putative miRNAs from each organism (Figure 1).

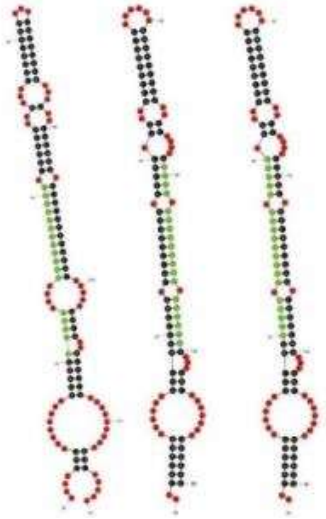

Figure 1. Predicted pre-miRNA stem-loop structures of selected miRNAs from *A.thaliana*. Mature miRNAs start and end points are shown by green color.

For each organism, average sequence length with a median for identified pre-miRNAs, mature miRNAs, average GC % content for pre-miRNAs with median and min-max values were calculated, and they are shown in Figure 2. Minimal folding free energy index (MFEI), which is calculated from the minimum folding free energy (MFE), sequence length and %GC content of the pre-miRNA, differentiates miRNAs with typically higher MFEIs (0.67) from other types of cellular ssRNAs for which MFEIs were previously characterized; transfer RNAs (0.64), ribosomal RNAs (0.59), and mRNAs (0.62–0.66)(Schwab et al., 2005). The low negative MFE values show the higher stability of the predicted miRNA (Zhang et al., 2007; Jin et al., 2008).

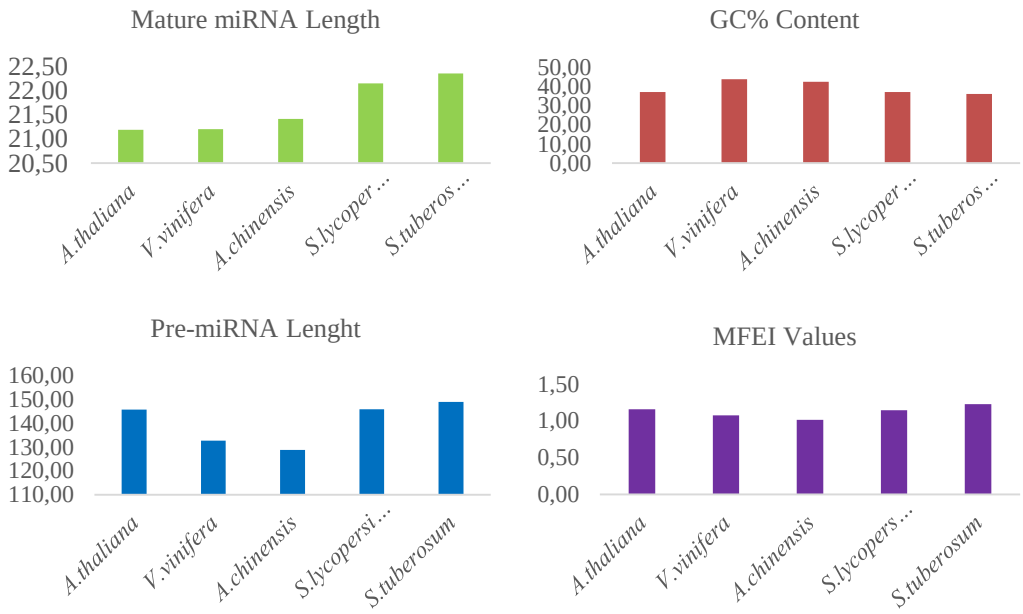

Figure 2. MFE and MFEI tables with minimum, maximum and median values for unique pre-miRNA sequences.

Prediction of putative miRNAs from genomes of different plant species enabled us to compare the variety of miRNAs across species. In the *A.thaliana* genome, we predicted as 93 putative miRNAs; in *S.lycopersicum* genome 57 putative miRNAs were predicted and analyzed. *S.tuberosum* had 61 putative miRNAs to be analyzed whereas, in *V.vinifera* genome, we predicted 43 putative miRNAs (Figure 3). In our previous study, we found 52 putative miRNAs in *A.chinensis* genome during the last study (Avsar and Esmaeili, 2015). According to our results, *A.thaliana* had the highest number of putative miRNAs in its genome whereas *V.vinifera* had the lowest number of miRNAs. Although the genome size of V. vinifera (~500Mbp) is larger than the *A.thaliana* (~135Mbp), the number of predicted putative miRNAs did not show the similar correlation. This may be caused by different evolutionary biogenesis characteristics of miRNAs across plant species.

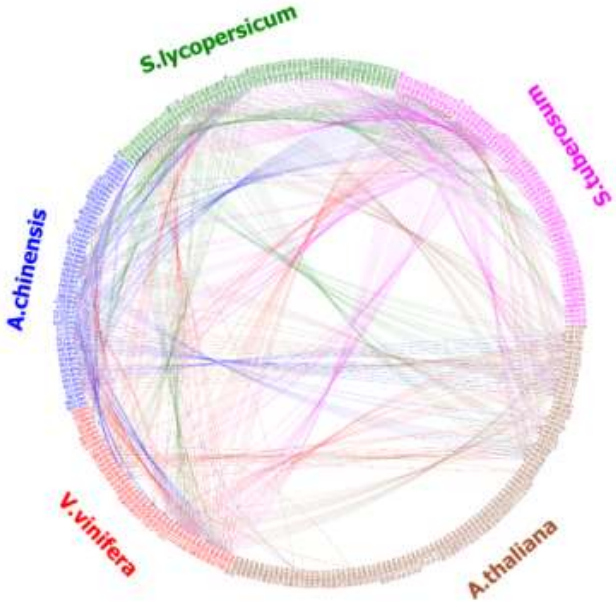

Figure 3. All miRNAs predicted from five organisms (Avsar et. al., 2016).
Link:http://APresenter.com/view.faces?id=2055757656

Between all those five plant species, some miRNA families were found commonly: miR156, miR157, miR160, miR162, miR167, miR169, miR170, miR171, miR172, miR319, miR390, miR396, miR398, miR399. Those common miRNAs are probably not "species-specific" type of miRNAs but have some critical regulatory roles including development, growth, modulation of auxin-response. All common miRNAs between organisms are shown in Figure 4.

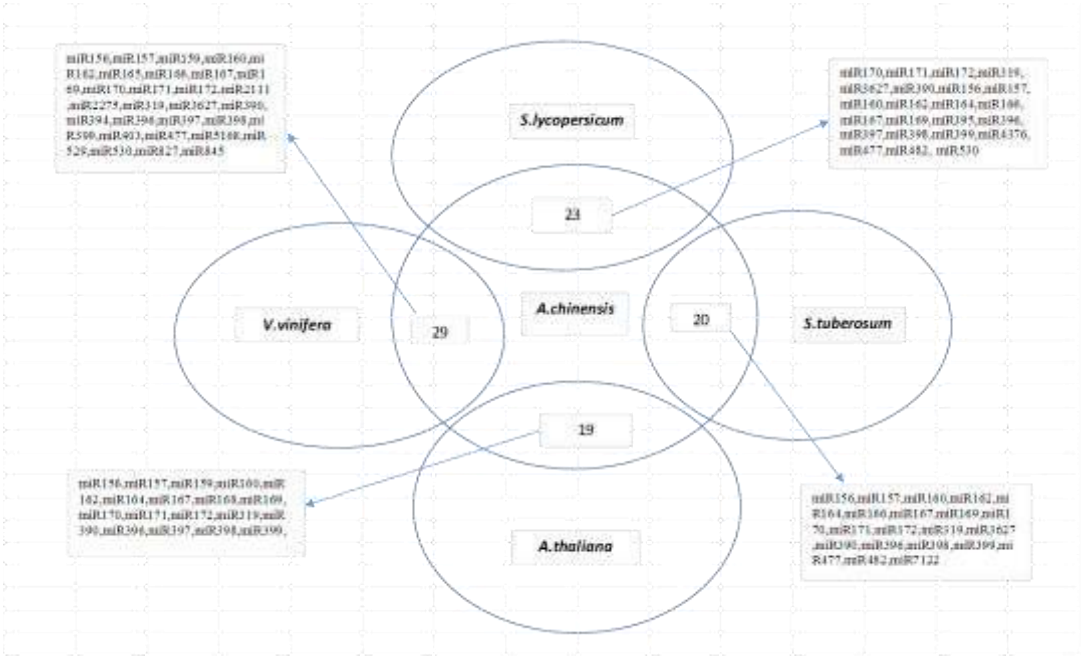

Figure 4. Common miRNAs between all organisms.

Clustering of putative miRNAs: The clustering of miRNA families of plant species showed that the higher similarity between *S.lycopersicum-S.tuberosum* than *V.vinifera-A.chinensis* (Figure 5). Huang et al. analyzed some other sequenced plant genomes to compare with the kiwifruit and they showed that the tomato had the closest evolutionary relationship (Huang et al., 2013) however regarding miRNA families clustering, grapevine showed more similarity to kiwifruit genome. These findings might be used for further evolutionary studies.

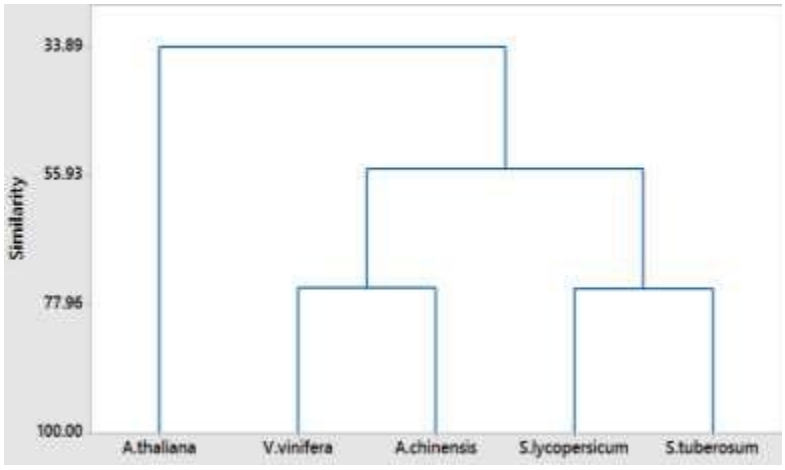

Figure 5. Clustering analysis for all species.

Targets of putative miRNAs and their annotations: Duplicate mature miRNA sequences were removed and the remaining mature miRNA sequenced were used for target annotations. These annotations were conducted to identify the miRNA targets in biological processes, molecular pathways, and cellular components.Based on the biological processes results, targets of *S.tuberosum* and *S.lycopersicum* putative miRNAs showed similarity as they have roles in metabolic processes, single-organism processes, response to stimulus and cellular processes. However, *A.chinensis* and *V.vinifera* had the similar functions mentioned above in addition to the cellular component organization and localization. *A.thaliana* miRNA targets were not identical to any organism since they had roles in different pathways (Figure 6).

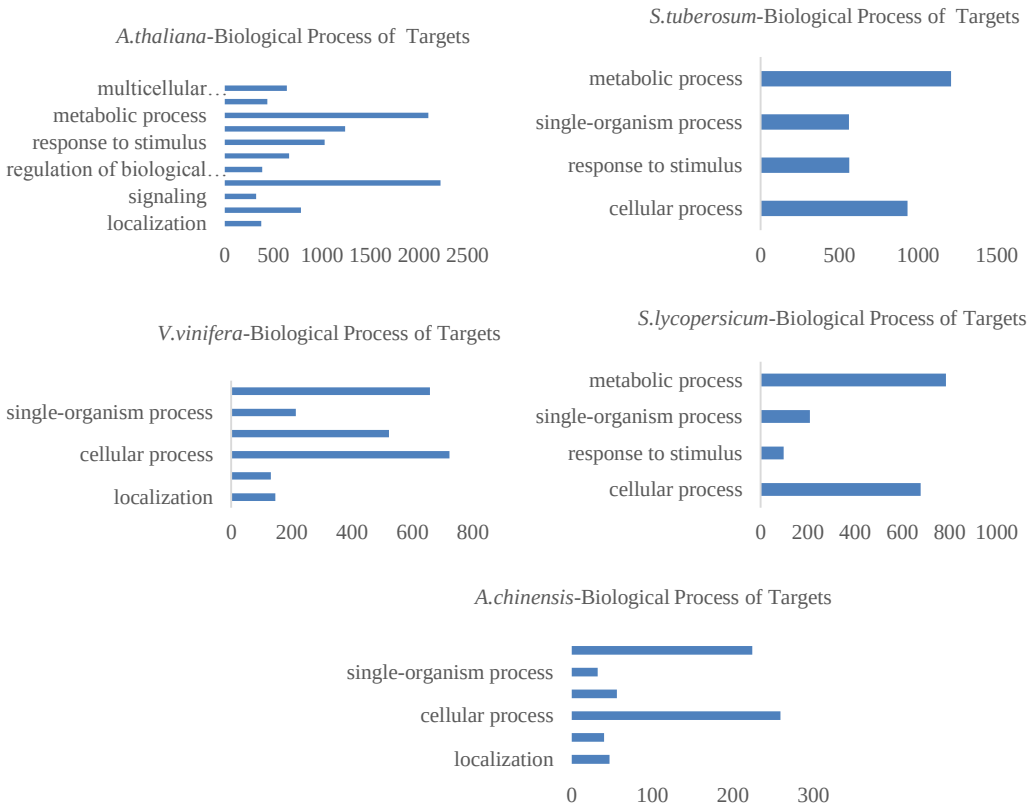

Figure 6. Blast2Go target annotations chart based on biological processes.

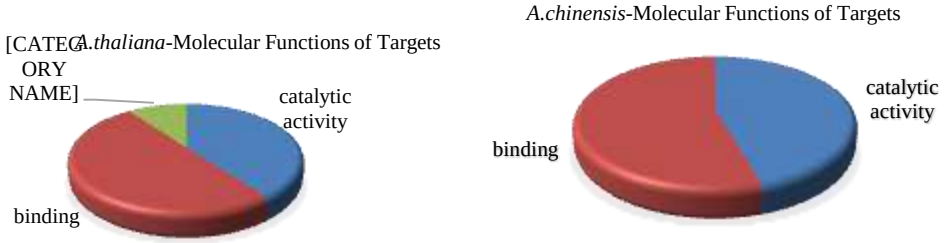
For the molecular functions of targets, almost all the organisms showed the similar results except for *A.thalina*. Putative miRNA targets are mostly found in catalytic activity and binding processes. In *A.thaliana*, additionally, nucleic acid binding transcription factor was found. In *A.chinensis*, putative miRNA targets were primarily found in binding activities (Figure 7).



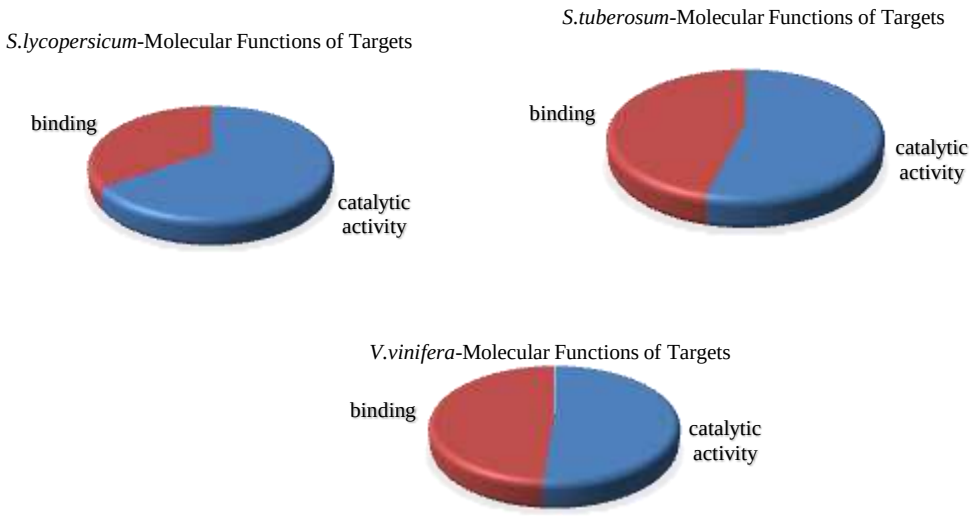


Figure 7. Blast2Go target annotations chart based on their molecular functions.

Representative miRNA families and the expression analysis of predicted miRNAs: We cannot determine the absolute copy number of each miRNA families by indeed since some miRNA genes may be covered by more than one while others may not be covered at all. However, the representation of each miRNA within the dataset provides us to estimate its prevalence on the genome. According to those results, miR169 and miR156 families were highly represented in the *A.thaliana* genome. In *S.lycopersicum*, miR5303 families had the highest representative whereas in *S.tuberosum* miR7984 families were represented mostly. miR3631 families were the most represented in *V.vinifera* genome however in *A.chinensis*, miR156 families and miR171 families were highly represented.

1,527,298 and 300,445 EST sequences were retrieved from NCBI database for *A.thaliana* and *S.lycopersicum*, respectively. 250,136 and 460,107 EST sequences were retrieved for *S.tuberosum* and *V.vinifera*, sequentially. Finally, 132,583 *A.chinensis* EST sequences were obtained from NCBI. All EST databases were built separately and analyzed in silico. According to those results, the highest number of expressed miRNA families (miR160, miR167, miR171, miR398, miR5654, miR5656, miR8170, miR826, miR830, miR840, miR860, miR869) was found in *A.thaliana* genome whereas the least number of expressed miRNA families was found in *A.chinensis* (miR535). This may result from the number of EST sequences in the database that we used since *A.thaliana* had the highest EST sequences and *A.chinensis* had the lowest EST sequences in their databases. All other expressed miRNA families for all organisms are shown in Table 1.

Table 1. *In silico* expression analysis on all plant species.

A.thaliana	miR160, miR167, miR171, miR398, miR5654, miR5656, miR8170, miR826, miR830, miR840, miR860, miR869
A.chinensis	miR535
S.lycopersicum	miR157, miR156, miR172, miR482, miR5303, miR5304, miR7983, miR7997
S.tuberosum	miR6027, miR156, miR172, miR396
V.vinifera	miR3623, miR172, miR3633, miR3634, miR396, miR397, miR827

Conclusions

In this study, *A.thalinana*, *V.vinifera*, *S.lycopersicum* and *S.tuberosum* were used for the comparison of miRNA repertoire since they were also performed for better understanding the genome of *A.chinensis* in draft genome sequencing article (Huang et al., 2013). *A.chinensis* is the first sequenced genome in the order of Ericales, so our study will be a good source for comparative genomics and evolutionary studies in the asterid lineage. It has also substantial duplication events after the divergence from tomato and potato and the genome structure might be affected by gaining some additional properties. In our study, we predicted that *A.chinensis* harbored some putative miRNAs that were not found in *S.tuberosum* or *S.lycopersicum* and these different putative miRNAs might result from the divergence events. Kiwifruit also has a rich source of vitamin C and other nutritional compounds so those identified miRNAs might have some regulatory roles on the pathways. In other words, kiwifruit genome will be an invaluable source of better understanding genome evolution and improvement of some agronomical properties in other plants including nutrient metabolism, disease resistant, sex determination and polyploidy events and the findings in the presented study will help to research community to elucidate the roles of miRNAs in these critical pathways.

Abstract

Heavy clay soils having firmly structure make difficult to growth of plant roots. Humic substances contribute to plant growth and development by improving the structure of the soil. This research was carried out in order to determine the effects of humic substance application on grape cluster and shoot characteristics of "Trakya Ilkeren" variety. In heavy clay soil conditions, humic substance (total humic + fulvic acid 15%, total organic matter 10%, water soluble K_2O 2%, pH 8-10) was applied to soil and foliar in 2014-2015. In the study, humic substance was applied in pre-flowering and post-flowering stages on grapevines. The effects of humic substance application on cluster weight, cluster width, berry width, berry length and berry weight was found insignificant except for cluster length. The effect of humic substance on titratable acidity, pH, and maturity index was found to be significant except TSS. The highest TSS, and cluster weight was found on soil application while the highest berry weight, pH and titratable acidity obtained in foliar application of humic substance. The highest cluster weight, cluster width and berry length was found in soil application while cluster length, berry width and berry weight measured in foliar application of humic substance. The effect of humic substance application on leaf area and shoot length was found sıgnificant, but there was no effect on shoot diameter. In the study TSS, cluster weight, berry weight, pH and titratable acidity was affected positively on humic applications. According to results, the both humic substance application to the soil and foliar will be more effectively.

Keywords: *humic substance, grape, cluster, vegetative development, quality*

Introduction

In organic farming, the use of organic origin fertilizers such as compost and animal manure is supported. However, animal manure has only healed a certain part of the soil, there is no effect deeply. In addition, the intensive use of manure in farming increases the emergence of weeds. However, humic substances contribute to plant growth and development by improving soil structure. It also plays an important role in soil fertility and plant nutrition (Asgharzade and Babaeian, 2012). Natural sources "lignite" and "leonardite" are the most common sources of humic substances (Kutluca, 2007). Humic acid have also important roles in agriculture. They are the most active components of soils and organic composts that act directly on the plant (Chen *et al.,* 2004). There are some plants hormone-like structures in humic substances. Thus, they have a stimulating effect on growth in plants (Pizzeghello *et al.,* 2002). In particular, it has been noted that humic acid reduce the adverse effects of chemical fertilizers in viticulture (Akıncı, 2011).

Humic acid is a complex macro-organic molecule found in dissociated organic matter, peat, coal deposits and soils. When the humic acid applied to soil, It increase the germination capacity of the seed and multiplies the vitamin content of plants (Oğuz *et al.,* 2012). They are also a reserve for microorganisms thanks to elements such as C, N, S and P in their structure. Because of this features, humic acid enrich soil microflora (Yılmaz, 2007; Larcher, 2003). Ferrara and Brunetti (2007) stated that when the humic acid obtained from soil and compost applied to foliar in grapevine, it was significantly affected the quantity and quality of the product compared to control. It has been reported that application of both types of humic acid

to grapes causes a significant increase in berry length, diameter and weight. In the study of Flame Seedless grape variety, the best result was obtained by applying 0.1% humic acid in addition to a 1/3 cluster reduction after berry set (Mohamed, 2016). It has been reported that humic acid application increases berry weight, titratable acidity and maturity index at full bloom period in "Italia" grape variety (Ferrara and Brunetti, 2010; Akın, 2011). Ferrara and Brunetti (2010) reported that application of humic acid at a dose of 100 mg l^{-1} four times to soil during the full flowering period in the "Italia" grape variety increased the berry width, berry weight, titratable acidity and maturity index considerably. It has been reported that humic acid stimulate plant growth by increasing the uptake of macro elements by the plants (De Kock, 1955). Humic acid increasing microbial activity in the soil indirectly promote plant growth by stimutating hormones (Vaughan and Mc Donald 1976). Hafidi et al. (1995) reported that application of humic acid to soil increased the favorable phosphorus. However, Ferrara et al. (2008) has been stated that the reaction of humic acid to foliar application in table grape varieties is still limited and cannot be fully determined.

Akın and Alagöz (2016) obtained the highest yields from humic acid application in "Kabarcık" grape variety. Popescu and Popescu (2018) reported that the humic acids had a positive effect on grape growth and fruit quality when applied at the pre-bloom and fruit set stages. Researchers proposed that the humic acid concentration of 40 mgL^{-1} optimal application rate for grapevines.

In the study, the effects of humic substance application to the soil and foliar on shoot and cluster characteristics in "Trakya Ilkeren" grape variety, which was growing in heavy clay soil structure were investigated.

Materials and Methods

The research was conducted in the experimental vineyard of Ondokuz Mayıs University, Turkey in 2014-2015. The vineyard located at 41°21'52 N latitude and 36°11'29 E longitude with an altitude of 195 m and a distance of about 2.8 km from the Black Sea coast of Turkey. The research vineyard has 62.2% clay soil, pH 7.1 and 4.33% organic matter content. In the study; 10-year-old "Trakya Ilkeren" grape variety grafted on 5C rootstock was used. Spur pruned grapevines were trained onto double cordon with 3x1.5 m spacing. Grapevines were not irrigated, not fertilized and the water only received from rainfall. In the study, 22.5 mg/L humic substance per vine (total humic acid + fulvic acid 15%, total organic matter 10%, water soluble K_2O 2%, pH 8-10) was applied to the soil and foliar at pre-flowering and post-flowering periods. Each treatments were done within 5 L water. While the foliar sprays using a hand pressure sprayer, soil application was applied to the root region of each vines. Sample fruits were harvested at maturity stage from each replicates. In the study, the effect of the humic substance application on cluster weight (g), cluster width and length (cm), berry weight (g), berry width and length (mm), pH, titratable acidity (TA %) TSS (Brix %), maturity index (TSS / acidity), shoot length (cm), shoot diameter (mm), leaf area per shoot and total leaf area (cm^2) was investigated. Leaf areas were calculated non-destructively [$-1.41 + 0.527x(W^2) + 0.254x(L^2)$] according to Elsner and Jubb (1988). Leaf width (W) and leaf length (L) were used to calculate leaf areas.

Statistical Analysis

Complete randomized block design with three replications were used and the mean of the measurements was evaluated in the study. Vegetative growth and cluster characteristics were measured in four grafted vines of each replication. The data were analyzed by two-way analysis of variance (ANOVA) to test main effects and interactions between for application and year. Data analysis was performed using SPSS 16.0 for Windows. Results studied were presented as means and a pooled standard error of mean (SEM). Differences among means were detected using Duncan's multiple range tests at significance levels of ($p<0.05$).

Results and Discussion

The effects of the humic substance application to the soil and foliar on cluster and berry weight, cluster width and length, berry width and length in "Trakya Ilkeren" grape variety are given in Table 1. In the study, while the effects of humic substance application on cluster and berry weight, cluster width, berry width and length was found to be insignificant, it was found significant in cluster length. However, it has been found that the application of humic substance from the soil and foliar increased the cluster and berry weight, and cluster width and cluster length, compared to control vines. The cluster weight was found to be 613.97 g on control grapevines; 620.44 g on foliar application and 621.63 g on soil application. In the research, the highest cluster width (16.52 cm) and cluster length (23.86 cm) was obtained in the foliar application. Berry weight was determined as 4.91 g. on control grapes; 5.07 g. on foliar application and 5.19 g. on soil application. The highest berry width (20.49 mm) was found on foliar application, while the highest berry length was obtained on soil application (19.51 mm). Humic substance had a significant effect on cluster length and the highest cluster length was obtained in foliar application (23.86 cm). Ferrara and Brunetti (2008) stated that when the humic substance was applied at 5 and 20 mg L^{-1}, the average yield was 32.2 and 29.9 kg, respectively, whereas in the control group this was only 28.2 kg. Asgharzade and Babaeian (2012); reported that the humic acid had a significant effect on cluster length and the highest cluster length was obtained in 300 mgkg-^{1} humic acid.

Table 1. The effects of humic substance applications on cluster characteristics in "Trakya Ilkeren" grape variety

Applications	Cluster weight (g)	Cluster width (cm)	Cluster length (cm)	Berry weight (g)	Berry width (mm)	Berry length (mm)
Control	613.97	16.21	21.74 b	4.96	20.35	19.46
Foliar	620.44	16.72	23.86 a	5.19	20.49	19.22

Year* Applications	ns	ns	ns	ns	ns	ns

* Pooled SEM: Standart error of the means (NS. $p>0.05$; * .$P\leq0.05$; **. $P<0.05$)

The effects of humic substance application to the soil and foliar in "Trakya Ilkeren" grape variety on the maturity parameters such as TSS, pH, titratable acidity and maturity index are given in Table 2. While the effect of humic substance application to the soil and foliar on TSS in "Trakya Ilkeren" grape variety is not significant, the effect on pH, titratable acidity and maturity index was found to be more important than control. The amount of TSS in the soil application was 18.01%, 17.42% in foliar application and 17.85% in control grapes. The maturity index is statistically significant among applications. Maturity index was determined as 46.97 in control grapes, 39.15 in soil application and 38. 55 in foliar application. Titratable acidity was obtained as 0.49% in foliar application, 0.46% in soil application and 0.36% in control grapes. The pH level was measured as 4.16 in the foliar application, 4.06 from the soil application and 3.57 in the control grapes. In our study, the effect of humic substance application to the soil and foliar on the TSS was insignificant, but it was slightly higher than the others in soil application. According to Köse et al. (2016), humic substance application to the soil significantly increased TSS in "Narince" and "Alphonse Lavallée" grape varieties

compared to control. It was reported that humic acid application in "Erciş" grape variety no significant effect on yield, cluster weight, berry weight and amount of juice but it was affected on TSS and titratable acidity (Yaşar, 2005). Mostafa and Akın (2017) was recommended the application of 333 ml of humic acid/5 liters of water from the soil to increase grape yield, cluster weight and 100-berry weight in "Italia" grape variety. In this regard, Ferrara and Brunetti (2010) reported that application of humic acid at 100 mg/L four times in full bloom period in grape variety significantly increased berry width and weight, titratable acidity and maturity index values. Akın (2011) reported that humic acid application increased yield, berry weight, and red and blue color density values in the "Horoz Karası" grape variety.

Table 2. The effects of humic substance applications on maturity parameters in "Trakya Ilkeren" grape variety

Applications	TSS (Brix%)	Maturity Index	pH	Titretable Acidity (TA %)
Control	17.85	48.07 a	3.57 b	0.38 c

* Pooled SEM: Standart error of the means (NS. $p>0.05$; * .$P\leq0.05$; **. $P<0.05$)

The effects of humic substance application to the soil and foliar on leaf area, shoot length and shoot diameter of "Trakya İlkeren" grape varieties are given in Table 3. While the leaf area and shoot length are significantly influenced by humic substance application, the effect on shoot diameter is not significant. The leaf area was measured as 2796.6 cm^2 in soil application. The shoot length (261.2 cm) and shoot diameter (9.97 mm) were found to be the highest in foliar application.

Table 3. The effects of humic substance applications on vegetative characterictics in "Trakya Ilkeren" grape variety

	Leaf area (cm^2)	Shoot length (cm)	Shoot Diameter (mm)
Control	2328.0 b	184.81 b	9.69
Foliar	2323.2 b	261.62 a	9.97

It has been reported that humic acid directly affect the ion exchange, convert plant nutrients into useful form, increase microbial activity and induce plant growth indirectly with the resulting hormones. In our study, the effect of humic substance application on vegetative development was significant but did not affect shoot diameter. According to Köse et al. (2016), although the effect of humic substance application to the soil application on vegetative development in "Narince" and "Alphonse Lavallée" grape varieties was not

significant but it was determined that the growth of shoots was reduced slightly. On the other hand, Ferrara and Brunetti (2008) stated that foliar application of humic substance effected positively on qualitative and quantitative parameters of "Italia" grape.

Conclusion

In the study, both applications of humic substance to soil and foliar were found beneficial even if there is no difference between applications, statistically. The positive effect was found in terms of soil humic substance application on cluster weight and TSS. It was seen that the positive effect of humic substance application on TSS will contribute to the increase of quality, especially for organic grape production, early ripening varieties and under greenhouse cultivation. At the same time, the obtained results show that it would be very useful to carry out in different grape varieties and different application doses. The combined applications both soil and foliar will be give more positive results.

Abstract

Most of the researchers say that mixed growing has lots of advantages and it can produce more balanced feed compared to sole production. Prominent advantage of forage rape and pea is that they can be grown during the winter period in our region. Thus, there is no irrigation demand and this mixture reach the harvesting stage before the sowing time of main warm season crops such as corn, tobacco, sunflower, sugar beet, watermelon, melon and other vegetables. There is a big roughage gap in our region, as well as in Turkey. Aim of this study was to determine suitable forage rape and forage pea cultivars, their binary mixture and harvesting time without causing any restriction to warm season crops. The research was designed as split plot in randomized blocks with four replications and carried out in coastal Central Black Sea Region. Forage rape (Cv. Lenox) was grown as binary mixtures with Gölyazı, Kirazlı, Ulubatlı, Tamkoc (Turkey), Letin, Adam (Croatia) and Kosmaj (Serbia) cultivars of forage pea. All the cultivars were grown solely, also. The harvests were made at budding and blossoming periods of forage rape. Letin, Kirazlı and Gölyazı forage pea cultivars started blossoming one week earlier than forage rape. Average blossoming duration of these was 138 days after sowing. Blossoming time of Ulubatlı cultivar was the same with forage rape, but Adam, Tamkoç and Kosmaj blossomed later. Plant height of sole forage rapes (63.5 cm) were higher than mixed (55.9 cm) ones. While the highest forage pea was Kirazlı cultivar (78.2 cm), the shortest one was Adam cultivar (47.0 cm). Forage yield and quality parameters of mixed plots were generally higher than sole forage rape plots.

Keywords: *Forage rape, Forage pea, Mixture, Harvesting time.*

Introduction

There is scarcely less opportunity to increase agricultural lands in Turkey as well as in the world. However, on the other hand, population is growing day by day. In this case, we should use more effectively available agricultural areas. One of these ways is to apply mixed growing system. Light cannot be deposited by green plants for using later. If there was not a limit to supply water and nutrients, dry matter production depends on light holding capacity of green plants. In successful mixed growing systems, light holding capacity of plants increase. Actually, plants grow up mixed in grassland areas. We should establish forage crops as mixof a few suitable species similar to natural grassland areas (Acikgoz, 2001).

Rape plants have a rapid growing ability and they can reach seed ripening period in 4-5 months. Even though, rape is mainly used as oil crop (Acikgoz, 2001 and Gizlenci *et al.*, 2003), recently forage rape farming start to increase in the aim of to meet forage gap. Forage rape can be used as fresh herbage, hay or silage to feed the ruminants. Nevertheless, there are some anti-nutrients such as erucic acid, glucocids and nitrate in rape tissues, for this reason it is necessary to take some precautions when feeding the livestock with forage rape.

In order to decrease detrimental effects of anti-nutritional compounds, forage rape can be grown mixed with other annual forage crops. Especially forage pea is very suitable to grow mixed with forage rape, because of its rapid growing ability, high yield and nutritional values and very tall plant high (Balakhial *et al.*, 2008; Khodaparast *et al.*, 2011 and Neely *et al.*,

2009). In our region forage rape has some advantages like rapid growing ability, higher forage yield and it can be grown rainfed conditions (because it grows vegetatively during the winter and spring periods). The aim of this study is to determine the best suitable forage pea cultivar in terms of forage yield, quality and growing stage when harvested in budding and blossoming stage of forage rape.

Material and Methods

The experiment was established according to randomized block design with 4 replicates. In the study, forage rape (*Brassica napus* L.) cv. Lenox, forage pea (*Pisum sativum* L.) cv. Gölyazı, cv. Tamkoç, cv. Ulubatlı, cv Kirazlı (Turkey), cv Kosmaj (Serbia), cv. Letin and cv. Adam (Croatia) were used. The study was carried out in experimental area of Ondokuz Mayis University, Agricultural Faculty during 2017-18 growing season. Consider the soil sample analysis, 8 kg da^{-1} phosphorus applied the whole experiment. N fertilizer was separated in 2 parts, one part in sowing time, the other part in spring was distributed by hand. The amounts of N were 10 kg da-1 for solely forage rape plots 6 kg da^{-1} for mixed plots and 3 kg da^{-1} for solely pea plots. There was no irrigation. The first harvest was performed at budding stage of forage rape (17.04.2018) and second harvest was at blossoming stage of forage rape (25.04.2018). Forage samples were analyzed by using NIRS device. The data were statistically analyzed with SPSS program.

Results and Discussion

Blossoming dates of cultivars and their differences from forage rape cv Lenox blossoming date one given Table 1. Forage rape cv Lenox started blossoming at 27.03.2018. Two forage pea cultivars Letin and Kirazlı were earlier than cv Lenox 12 and 7 days, respectively. Forage pea cultivars Ulubatlı and Gölyazı blossomed same date with Lenox. Compare to Lenox, Tamkoç and Adam 29 days, Kosmaj 41 day later blossomed.

Table 1. Blossoming dates of cultivar and differences

Cultivars	Blossoming date	Difference
Lenox	27.3.2018	-
Letin	15.3.2018	12 days earlier
Kirazlı	20.3.2018	7 days earlier
Ulubatlı	27.3.2018	0
Gölyazı	27.3.2018	0
Tamkoç	25.4.2018	29 days later
Adam	25.4.2018	29 days later
Kosmaj	07.5.2018	41 days later

There were significant differences among the cultivars grown in both as solely and as binary mixture in the point of plant height (Table 2). In general, plant height of forage pea cultivars decreased when they were grown as binary mixture with forage rape, except for Ulubatlı and Letin. The highest group was consists of Gölyazı, Kirazlı and Kosmaj in solely plots, while all of the cultivars took place the top group in binary mixture plots, except Ulubatlı and Adam.
In terms of hay yield significant differences amongst the cultivars in solely plots. Except for the earliest cultivar Letin, all of the cultivars were in the highest group. Hay yield was increased in all binary mixture plots. In binary mixture plots hay yield was determined as total of pea and rape. Probably high yielding forage rape might be prevented statistical differences amongst the forage pea cultivars. In mixture growing systems, land equivalent ratio (LER) value is generally increase, thus yield of mixture plots also is increase, compared to solely plots (Zeybek, 2017).

Table 2. Plant height and hay yields of cultivars grown as solely and binary mixture*

Treatments**	Plant height (cm)		Hay yield (kg/da)	
	Sole	Mix	Sole	Mix
Tamkoç	96.50bd	90.75ab	368.01a	780.33
Kirazlı	106.75ac	106.00a	260.46ab	607.19
Gölyazı	118.75a	104.75ab	387.17a	694.80
Ulubatlı	83.50d	87.66bc	327.40ab	559.28
Adam	82.25d	72.00c	282.01ab	599.88
Kosmaj	104.50ac	100.75ab	293.93ab	664.45
Letin	91.5cd	97.66ab	166.16b	571.80
Lenox	112.75ab	-	360.19a	-

*There is no significant difference ($p \leq 0.05$) amongst the figures indicated in the same letter within the same column

Crude protein, ADF and NDF ratios of cultivars can be seen in Table 3. Consider the crude protein ratios, there are significant ($p \leq 0.05$) differences amongst the cultivars in both solely and mixture plots. All the cultivars, except cv Kosmaj took place in the highest group in solely plots while the top group was consisted of Ulubatlı, Adam and Tamkoç cultivars in mixture plots. Crude protein content of forage rape was significantly lower than the forage pea cultivars. Even though, there were significant differences amongst the cultivars in the point of ADF and NDF contents, the values of forage pea cultivars close to each other. Higher values of forage rape cultivar Lenox might be caused statistical differences. ADF ratios varied between 28% and 34% while NDF contents ranged from 43% to 48% of forage pea cultivars (Table 3).

Table 3. Crude protein, ADF and NDF values of cultivars grown as solely and binary mixture*

Treatments**	Protein (%)		ADF (%)		NDF (%)	
	Sole	Mix	Sole	Mix	Sole	Mix
Tamkoç	21.67a	20.41ab	31.54b	28.69ab	46.9775	43.25ab
Kirazlı	20.95ab	18.52b	28.57b	30.40ab	43.5325	45.41ab
Gölyazı	21.30ab	19.66b	29.13b	31.25ab	43.0800	46.06ab
Ulubatlı	21.77a	24.86a	29.96b	27.27b	45.1700	40.40b
Adam	18.96ab	20.80ab	32.71ab	31.09ab	46.3425	45.01ab

Lenox	12.25c	-	38.55a	-	50.1200	-

*There is no significant difference ($p \leq 0.05$) amongst the figures indicated in the same letter within the same column

Some mineral contents of cultivars were given in Table 4. In terms of Ca, K, Mg and P ratios of hay, there were significant differences ($p \leq 0.05$) amongst the cultivars in both solely and mixture plots. Ca, K, Mg and P contents of forage pea cultivars were ranged as follows: Ca: 1.04%-1.21%; K: 2.67%-3.90%; Mg: 0.22%-0.25% and P: 0.35%-0.51%. Mineral contents of forage pea cultivars generally higher than forage rape (Table 4).

Table 4. Ca, K, Mg and P contents of cultivars grown as solely and binary mixture*

Treatments**	Ca (%)		K (%)		Mg (%)		P (%)	
	Sole	Mix	Sole	Mix	Sole	Mix	Sole	Mix
Tamkoç	1.16ab	1.13ab	3.51a	3.40ab	0.25a	0.22ab	0.46a	0.42b
Kirazlı	1.16ab	1.09ab	3.30a	3.13b	0.24a	0.22b	0.43ab	0.39b
Gölyazı	1.17a	1.12ab	3.32a	3.33ab	0.25a	0.22b	0.43ab	0.42b
Ulubatlı	1.15ab	1.21a	3.59a	3.90a	0.24ab	0.25a	0.45ab	0.51a
Adam	1.12ab	1.16ab	3.29a	3.45ab	0.22ab	0.23ab	0.40ac	0.43b
Kosmaj	1.08ab	1.04ab	2.67b	2.79b	0.25a	0.25a	0.35c	0.36b
Letin	1.16ab	1.15ab	3.04ab	3.07b	0.23ab	0.23ab	0.38bc	0.39b
Lenox	1.07b	-	2.65b	-	0.21b	-	0.34c	-

*There is no significant difference ($p \leq 0.05$)amongst the numbers indicated the same letter within the same column

Conclusion

Ulubatlı and Gölyazı forage pea cultivars blossomed exactly same date with forage rape cultivar Lenox. In the point of high yield, quality parameters and growth stage conformity we can recommend Gölyazı cultivar to grow with forage rape cv Lenox in coastal area of Central Black Sea Region.

Abstract

Researchers and farmers have paid more attention to chicory recently, because of its palatability, high yield, nutritive value, digestibility, kept greenery throughout the summer period, deep and strong root system and drought resistant ability. In addition, it has some positive effects on animal health. Chicory is very common in natural areas of Turkey. This study was conducted according to randomized block design with three replicates in Samsun conditions in 2017. In the study, chicory (C), orchardgrass (OG) and red clover (RC) were grown as solely and binary mixture in rain fed conditions. Binary mixtures were 80% C + 20% OG, 60% C +40% OG, 40% C + 60% OG, 20% C + 80% OG, 80% C + 20% RC, 60% C + 40% RC, 40% C + 60% RC, 20% C + 80% RC. Harvests were made when chicory plants reached 25 cm average plant height. Three cuts were performed (twice in June and once in July) in 2017. Only chicory plants could reach the harvest stage for the third cut. The highest fresh yields was 55.7 and 17.7 t ha^{-1} at the 20% C + 80% RC mixture for the first and second cuts, respectively. Yield was getting decreased with each cutting sequence and it declined to 5.7 t ha^{-1} for the third cut. In totally, 20 % C + 80% RC binary mixture gave the highest yield. Total fresh yield was determined between 65.1 – 8.8 ha^{-1}. The highest hay yield was obtained from the treatments contain red clover as follows; 40 % C + 60 % RC, 100 % RC, 20 %C + 80 % RC, 80 % C + 20 % RC and 60 % C + 40 % RC (respectively; 12.30, 12.00 , 11.50 , 10.40 and 9.90 t ha^{-1}) . Crude protein ratios were 24.1 –16.1 % in the first, 26.9 – 17.5 % in the second and 22.9 – 20.3 % in the third cut. In the first, second and third cuts ADF ratios were 32.4 – 24.1 % , 33.5 – 20.4 % and 23.6 – 20.1 % ; NDF contents were 54.6 – 34.3 % , 58.2 – 34.0 % and 35.0 – 31.7 % , respectively.

Keywords: *Chichory, Orchardgrass, Red Clover, Mixture Rates.*

Introduction

In Turkey, in order to increase quality and amount of forage new species and cultivars were had to joined the agricultural system. In addition to alfalfa, sainfoin and vetch we need new alternative forage species. New cultivars were improved from alternative species and they were served to farmers in lots of developed countries. Other reasons to develop these cultivars are obtained varieties winter-hardly, drought-hardly and resist to other marginal lands. For example, there was a severe drought conditions in New Zealand in 1978, chicory genotypes survived these conditions and gave nutritious forage yield (Barry, 1998). Chicory has been used for different aims for a long time. But, recently it was focused on to use for forage. Chicory was eaten voluntarily by livestocks, its digestibility and nonstructural carbonhydrate levels are high, and has rich mineral content, resist to drought conditions. Chicory has some secondary compounds that prevent bloating and endoparasite in ruminants, it provides high forage especially during the summer period (Barry, 1998; Athanasiadou et al, 2007). It expands grazing period in pastures because it grows in summer period that lots of cool season perennial grass were dormant (Kemp et al, 2002). In study, suitable mixture forage yield and quality, of chicory, orchardgrass and red clover grown alone and binary mixture of chicory with the other species were investigated at grazing stage.

Material and Methods

This study was carried out in experimental area of Ondokuz Mayis University Agricultural Faculty in 2017. Average temperature and total rainfall were 13.4 ^{0}C and 386.2 mm during the study period of 2017 (between January and July). The study was established according to Randomized Block Design with 3 replicates. Chicory *(Cichorium intybus L.)* (C) with orchardgrass *(Dactylis glomerata L.)* (OG) and red clover *(Trifolium pratense L.)* (RC) were used as plant materials. These species were sown as solely and binary mixtures as follows: 80 % C + 20 % OG, 60 % C + 40 % OG, 40 % C + 60 % OG, 20 % C + 80 % OG and 80 % C + 20 % RC, 60 % C + 40 % RC, 40 % C + 60 % RC, 20 % C + 80 % RC. Species were sown alternate rows with 20 cm row spacing. There was no irrigation. Harvests were made at grazing stage (imitating the grazing) when chicory plants reach to 25 cm plant heights during the growing season. Three cuts were performed (twice in June and once in July) in 2017. Only chicory plants could reach the harvest stage for the third cut. After harvest, green herbage weighed in solely plots, but in binary mixture plots firstly sorted species and weighed separately. During harvest 500 g sample was taken for each plot and dried in an oven at 60 ^{o} C temperature until constant weight. Then these samples grounded and analysed protein, ADF and NDF Analyses of grinded samples were performed in Foss NIRSystems (Hoy et al., 2002) Model 6500 Win ISI II v1.5 device by using IC-0904FE calibration program. Resultant data were subjected to statistical analyses according to randomized block design. All data obtained from this study was analyzed by using SPSS 17.0 program. The differences amongst the mean values were calculated according to DUNCAN test.

Result and Discussion

The results about plant height fresh and hay yield obtained from solely and binary of chicory with orchardgrass and red clover plots are given Table 1. In terms of plant height there were significant differences ($P \leq 0.05$) amongst the treatments in all cuttings. The highest plant height was determined as 44.4 cm for alone red clover but values of some of the other treatments were same highest statistical group. The lowest value was observed from orchardgrass with 29.9 cm. Average plant height of alone chicory plots was 31.2 cm. Majority of the plant height values were same statistical group in the second harvest and values ranged from 29.5 to 24.4 cm. The highest values were measured for alone chicory plots in the second harvest. Only chicory plants could reached the harvest stage for the third cut. The highest plant height was 20.2 cm for 60 % C + 40 % OG plot while the lowest was 13.2 cm for 40 % C+60 % RC plot in the third cut (Table 1). Plant height values were generally low because of the first year of the experiment.

Table 1.Plant height, fresh and hay yield values obtained from the treatments

Treatments	Plant height (cm)			Fresh yields (t ha^{-1})				Hay yields (t ha^{-1})

* There was not significant differences amongst to figures shown the same letter in the same column ($P<0.05$)

In consider the fresh yields there were significant differences amongst the treatments in all three cuts. The highest fresh forage yields were obtained from 40 % C + 60 % RC (50.5 t ha^{-1}) for 1. cut, from 20 % C + 80 % RC (14.9 t ha^{-1}) for 2. cut and from 80 % C + 20 % OG (4.92 t ha^{-1}) for 3. cut. Regard the total fresh forage yields, the highest values determined for 40 % C + 60 % RC, 20 % C + 80 % RC , 80 % C + 20 % RC and 60 % C + 40 % RC (Respectively 65.1 , 62.9 , 59.3 and 54.4 t ha^{-1}) fresh forage yields were decreased as cutting sequence advance. In general, the plots contain RC gave higher fresh forage yield (Table 1).

Significant differences were determined amongst the treatments in the point of hay yield in 3 cuts and total. Hay yields were varied between 10.2 and 2.2 t ha^{-1} in the first cut and the treatments contains RC generally gave higher hay yield. Hay yield were ranged from 3.2 to 0.7 t ha^{-1} in the second cut. Only chicory plants could reached the harvest stage for the third cut. The highest chicory yield was obtained from 80 % C + 20 % OG treatment as 1.0 t ha^{-1}, but 60 % C + 40 % OG treatment was also same statistical group in the third cut. Total hay yield was varied between 3.70 and 12.30 t ha^{-1}. The highest hay yields were obtained from 40 % C + 60 % RC, 100 % RC, 20 %C + 80 % RC, 80 % C + 20 % RC and 60 % C + 40 % RC treatments (respectively; 12.30 , 12.00 , 11.50 , 10.40 and 9.90 t ha^{-1}). The treatments contain RC, generally, gave higher hay yield (Table1). Frame (2008), indicated that red clover well adapted to humid and cool climates and heavy, clay soil and red clover mixtures gave higher yield in the first year of establishment. An experiment was conducted by Ayan et al., (1997) with alfalfa, sainfoin, red clover, timothy, smoot brome, orchardgrass and red fescue in rainfed conditions of Samsun. Species were grown as alone and binary mixtures. The highest hay yield was obtained from alone red clover (14.7 t ha^{-1}) and red clover + orchardgrass mixture (12.6 t ha^{-1}).

Crude protein, ADF and NDF contents of the hay obtained from the treatments are given at Table 2. In terms of crude protein ratio, there were significant differences amongst the treatment in all cuts, except for third cut. Crude protein contents were ranged from 16.1 % to 24.1 % in the first and from 17.5 % to 26.9 % in the second harvest and crude protein ratios of the treatments that contain red clover have higher values compared to the others. Crude protein ratios of chicory were between 20.3 % - 22.9 % in the third cut (Table 2).

Table 2. Crude protein, ADF and NDF ratios determined to the treatments *

Treatments	Crude protein ratio			ADF ratio			NDF ratio		
	1. cut	2. cut	3. cut	1. cut	2. cut	3. cut	1. cut	2. cut	3. cut
Chicory	18.6b	21.5b	22.3	24.1d	20.4e	20.9	34.3e	34.0e	32.0
Orchardgrass	16.8bc	17.5cd	-	32.4a	33.5a	-	54.6a	58.2a	-

Average	**20.1**	**22.8**	**21.4**	**28.7**	**25.5**	**22**	**45.5**	**44**	**33.1**

*There was not significant differences amongst to figures shown the same letter in the same column ($P<0.05$)

There were significant differences amongst the treatment in the first and second cut, in the point of both ADF and NDF ratios (Table 2). ADF ratios were changed between 24.1 – 32.4 % and 20.4 – 33.5 %, respectively in the first and second harvests. The lowest ADF content was determined in the alone chicory. According to American Forage and Grassland

Council (AFGC, 2009) standards, all forages obtained from this study were in prime and premium classes when regard the ADF contents.

The highest NDF ratio was 54.6 % for 100 % OG and 52.7 % for 20 % C + 80 % OG treatments in the first cut. The lowest value was obtained from alone chicory as 34.3 %. In the second cut, the highest ratio was 58.2 % for 100 % OG and the lowest was 34.0 % for 100 % chicory. NDF ratios of chicory was ranged from 31.7 % to 35.0 %, in the third cut (Table2). When we evaluate the forages based on AFGC standards, in consider to NDF contents, all samples, except for 100 % OG plots were in prime and premium classes.

Conclusion

In the light of the first year results, the highest forage yield was obtained from 40 % C + 60 % RC, 20 % C + 80 % RC and 80 % C + 20 % RC binary mixture treatments. In consider forage yield, crude protein, ADF and NDF contents, 40 % C + 60 % RC and 60 % C + 40 % RC binary mixtures might be recommended to Samsun and similar ecological conditions. But, to clear the recommendations for perennial forage crops, the study should carry out at least two year.

Abstract

Total phenol, antioxidant activity and flavonoid contents of olive leaves extract were determined as 12.13 mg GAE/g, 89.47 % and 32.65 mg CE/g catechin, respectively. While total phenol contents of olive leaves changed between 0.89 and 8.81 mg GAE/g depending on infusion time, antioxidant activity values ranged from 8.21 to 28.11%. Flavonoid contents of infusion varied between 2.71 and 14.81 mg CE/g catechin. While total phenol contents of decoction were determined between 1.81 and 8.41 mg GAE/g, antioxidant activity values changed between 10.41 and 25.33%. Also, flavonoid contents of olive leave decoction ranged from 8.67 to 37.44 mgCE/g. The most abundant compounds in olive leaves were oleuropein, hydroxytyrosol, caffeic, the flavone-7-glucosides, luteolin, apigenin and verbascoside. While luteolin contents of infusion changed between 0.09 and 0.91 µg/kg, this compound ranged from 0.14 to 0.89 µg/kg in decoction. While oleuropein content of infusion changed between 0.10 and 0.97 µg/kg, oleuropein contents of decoction samples varied between 0.13 and 0.87 µg/kg. In addition, rutin contents of decoction varied between 0.19 and 0.99 µg/kg. Also, caffeic acid contents of decoctions ranged from 0.09 to 0.83 µg/kg. Generally, phenolic compounds of decoction (except 10.min) were found higher than those of phenolic compounds of infusion. olive leaves can be received much attention as antioxidant sources due to its phenolic compounds. Because, there are considerably higher ration of by products arising olive leaves.

Keywords: Olive leaves, *Ayvalık* cultivar, antioxidant, phenol, flavonoid, phenolic compounds, infusion, decoction.

Introduction

Polyphenols are very important due to the natural antioxidant nactivity of these constituents. Plant extracts like infusion and decoction are natural alternatives to synthetic antioxidants as they posses similar or even higher antioxidant activity. Olive leaves have many useful pharmaceutical effects (Sabry, 2014). Several studies were conducted on the antioxidant activity, hypoglycemic and antimicrobial effect of olive leaves (Soni *et al*., 2006; Wang *et al*.,2008). Sabry (2014) reported that decoctions of the dried olive fruit and leaves taken orally for diarrhea and to treat urinary tract infections, and also hot water extract of the fresh leaves treated high blood pressure and bronchial asthma. The olive (*Olea europaea* L.) leaves are composed of 10% of the dry weight arriving at olive mills, and they are an agricultural waste of the olive oil industry (Goldsmith *et al*., 2014). The olive leaves refer to a mixture of leaves and branches from both the pruning of olive trees and the harvesting and cleaning of olives (Molina-Alcaide and Yanez-Ruiz, 2008; Vogel *et al*., 2015). In recent years, there has been great interest in the health effects of various herbal teas as infusion and/or decoctions. Olive leaf tea is one of the most common, traditional herbal teas used among Mediterranean people to treat several diseases. Oleuropein is the most abundant polyphenol of olive leaves prevented cardiac disease by protecting membrane from lipid oxidation (Somova *et al*., 2003; Molina-Alcaide and Yanez-Ruiz, 2008; El and Karakaya, 2009). Pereira *et al*., (2007)

suggested that olive leaves may be used in infusions, allowing a considerable intake of bioactive compounds. The aim of present study was to determine antioxidant activity, total phenol and flavonoid contents and phenolic compounds of olive leave infusion and decoctions prepared at different heating times in hot water at 90 °C.

Material and Methods

Olive leaves (the cultivar *ayvalık*) were randomly collected from all round of each tree at the same time and height from ground in Mersin (Mut) province in South of Turkey in October 2016. The olive trees have ten years old. They grow in dry ground. After leaves were collected, they were transferred to Laboratory in cool bag, and kept at 4 °C.

Sample extraction of olive leaves

Phenolic compounds were extracted according to Singleton, *et al*., (1999) with some modifications. 4 g of each sample was added to 10 ml of acetone (80% v/v). The mixture was sonicated for 15 min, followed by centrifugation at 6000 rpm for 15 min and the supernatants were collected. These steps were repeated twice. The extract was concentrated at 37°C in a rotary evaporator under vacuum. Prior to injection, the extract was filtered through a 0.45 µm nylon filter. All analyses were performed in triplicate.

Extraction of phenolic compounds with infusion and decoction

For infusion, ground olive leaves (about 6 g) were added into boiled water (200 ml) at 90 °C, and separately infused for 1., 3., 5., 7., and 10. min. Then mix was filteres by a Büchner funnel. After extract was lyophilised, they were analysed by HPLC by re-dissolving in water. For decoctions, each ground olive leave sample (about 6 g) was bolied in 200 ml water for 1., 3., 5., 7., and 10. min at 90 °C. Following processing is the same such as in infusion processing.

Total phenol content

Total phenol contents of olive leave extracts were determined with the Folin-Ciacueltau (FC) reagent according to Yoo *et al*.,(2004). 1 ml of Folin–Ciacueltau was added into samples, and mixed for five minutes. After 10 mL of Na_2CO_3 was added into mix, the final volume was completed to 25 ml with distilled water. At the end of 1 hours, sample was measured in 750 nm in spectrophotometer. The results were given as mg GAE/100 g.

Antioxidant activity

The antioxidant activity was determined with DPPH (1,1-diphenyl-2-picrylhydrazyl) (Lee *et al*., 1998). the extract was mixed with 2 mL methanolic DPPH, and the mixture was shaken, and kept at room temperature for 30 min. The absorbance was measured at 517 nm.

Total flavonoid

Total flavonoid content was estimated according to Dewanto *et al*., (2002) and used Catechol as standart.

Determination of phenolic compounds

Total flavonoid content was estimated according to Juhaimi et al.,(2018) and used Shimadzu-HPLC equipped with DAD detector and Inertsil ODS-3 (5µm; 4.6 x 250mm) column.

Statistical analyses

All results were stated as mean±standard deviation (MSTAT C) of fruit samples (Püskülcü and İkiz 1989)

Results and Discussion

Total phenol, antioxidant activity, and flavonoid contents of olive leaves infused and decoctioned in boiled water at 90 °C are given in Table 1. While total phenol contents of olive leaves infused change between 0.89 and 8.81 mg GAE/g depending on infusion time, antioxidant activity values ranged from 8.21 to 28.11%. Flavonoid contents of infusion varied between 2.71 and 14.81 mg CE/g catechin. All properties of olive leave infusion

increased together with infusion times. According to infusion results, it is considered that optimum infusion time can be 7. min due to the highest bioactive substance increasing. The total phenol, antioxidant activity and flavonoid contents of olive leave decoction increased till 7. min of decoction processing (except flavonoid). This reduction may be probably due to the reduction of bioactive substances exposed to higher temperatures at about 90 °C. While total phenol contents of decoction are determined between 1.81 and 8.41 mg GAE/g, antioxidant activity values changed between 10.41 and 25.33%. Also, flavonoid contents of olive leave decoction ranged from 8.67 to 37.44 mg CE/g. Total phenol, antioxidant activity value and flavonoid contents of infusion were found lower when compared with results of decoction during heating. But, antioxidant values of decoction were found low after from 7. min of infusion. This situation can be probably due to affected of phenolic compounds from continuously boling at 90 °C. The total flavonoid contents of fresh and dried olive leaves changed between 3.4 and 11.78 to 6.23 to 21.47 mg CE/g, respectively (Abaza *et al*., 2011). The total phenol contents of olive leaf extracts ranged from 9.07 to 13.68 and 16.52 to 24.93 mg GAE/g, respectively (Abaza *et al*., 2011). Also, solvent polarity will play a key role in increasing phenolic solubility. The increase in heating time resulted in an increase of phenolic and flavonoid contents in all samples. Lafka *et al*., (2013) reported that olive lşeave extracts exhibited 18.8% (n-propanol extract) to 55.0% (ethanol extract) antioxidant activity. Olive leaves could be a low-cost renewable and abundant source of phenolic antioxidants, with potent use in fatty foods and medicinal herbal teas (Wissam *et al*., 2016).

Table 1. Bioactive properties of infusion and decoctions of olive leaves

Time	Infusion			Decoction		
	Total Phenol mg GAE/g	Antioxidant activity (%)	Flavonoid mg CE/g	Total Phenol mg GAE/g	Antioxidant activity (%)	Flavonoid mg CE/g

*mean±standard deviation; **Values within each column followed by different letters are significantly different ($p<0.05$)

The phenolic compounds of leave infusion and decoctions are shown in Table 2. The most abundant compounds in olive leaves were oleuropein, hydroxytyrosol, caffeic, the flavone-7-glucosides, luteolin, apigenin and verbascoside. While phenolic compounds of infusion increase depending on infusion times, phenolic compounds of decoction decreased after from 7. min of decoction processing. Generally, luteolin, catechin, hydroxytyrosol, caffeic, oleuropein and rutin contents were found high in both infusion and decoction during heating.

*mean±standard deviation; **Values within each row followed by different letters are significantly different ($p<0.05$)

While luteolin contents of infusion change between 0.09 and 0.91 µg/kg, this compound ranged from 0.14 to 0.89 µg/kg in decoction. While oleuropein content of infusion changed between 0.10 and 0.97 µg/kg, oleuropein contents of decoction samples varied between 0.13 and 0.87 µg/kg. In addition, rutin contents of decoction varied between 0.19 and 0.99 µg/kg. Also, caffeic acid contents of decoctions ranged from 0.09 to 0.83 µg/kg. Generally, phenolic compounds of decoction (except 10. min) were found higher than those of phenolic compounds of infusion. These differences can be probably due to more boiled of olive leaves at 90 °C. In previous study, Pereira *et al*., (2007) reported that caffeic acid was found as 1% of total phenolics. The amount of the phenolic present in the aqueous extract revealed a high amount of these compounds. The amount of phenols extracted at 90 °C increased with increasing extraction time up to 7. min of decoction processing. The differences detected in

olive leave extraction could be related with the times of infusion and decoction. Briante *et al*., (2002) reported that the phenolic compounds of olive leaves vary also at the time of fruits maturation. The chromatographed results of infusion and decoction of olive leaves were found different to the corresponding extracts. The extraction of dried leaves with hot water increased the extraction of certain phenolic compounds, when compared with methanol:water extraction (Silva, 2004). Silva *et al*., (2006) reported that fresh and dried olive leaves contained 11.6-17.4 and 11.7-40.1 g/kg total phenol, respectively. As far as known, there are no reports concerning the study of total phenol contents, antioxidant activity and phenolic compounds of both infusion and decoctions of the cultivar *Ayvalık* olive leaves.

Conclusion

So, olive leaves can be received much attention as antioxidant sources due to its phenolic compounds. Because, there are considerably higher ration of by products arising olive leaves.

Abstract

The study was performed with shoot tips that were selected from plum genotype displaying remarkable rootstock potential. The aim of this study was to determine the most appropriate protocol for the propagation of different plum genotype in vitro. The shoot tips of the selected plum belonging to Prunus divaricate species were surface-sterilized with sodium hypochlorite (15%) for 10 minutes. Aseptic culture was established on hormone free (HF) Murashige and Skoog (MS) and shoot tips were cultivated for four weeks at initiation medium. After establishment of aseptic culture, proliferation capacity of shoots was evaluated on HF MS medium containing with 30% sucrose and 8% agar and on HF MS media supplemented with different concentration of thidiazuron (TDZ), naphthalene acetic acid (NAA), gibberellic acid (GA3) and Indole-3-butyric acid (IBA). The lowest proliferation capacity (0.75) was found in HF medium and shoots did not exhibit signs of hyperhydricity (vitrification). At the same time, the highest incidence of vitrification (33%) was observed in the medium containing 0.75 mg/l TDZ, 0.5 mg/l NAA, 0.5 mg/l GA3 and 0.5 mg/l IBA with proliferation rate being 1.21. The highest proliferation rate (2.26) was achieved in the medium with similar hormonal composition as previous one with exception of TDZ concentration (1.5 mg/l). The results of the study suggest that TDZ exhibits great effect on proliferation rate and incidence of vitrification in this plum genotype.

Key words: *In vitro, rootstock, proliferation, vitrification.*

Introduction

Due to the special ecological conditions in Turkey, many species and cultivars of fruits are grown commercially. Stone fruits have taken substantial position in fruit cultivation both in Turkey and in the world. In Turkey, stone fruits production is accounted of approximately 15% in total fruit production. According to Turkish Statistical Institute (TUIK, 2018) data, production amount of stone fruits are arranged in order; apricot, nectarine, cherry, plum and sour cherry, respectively. Turkey has ranked first in apricot production with 730.000 t in 2016 and 985.000 t in 2017. Between the mentioned years, production increased by 34.9% (TUIK, 2018). Size-controlling rootstocks are needed for cultivation of table apricots especially in Mediterranean and Aegean regions. In both regions, apricots are mostly grown on plum rootstocks. The most important reasons for choosing plum rootstocks are that these rootstocks perform well in the heavy soils in the Mediterranean region and can reduce the tree size. Plums belong to the species of genus Prunus (family Rosacea) which have edible fruits. The plum which grows naturally in Anatolia has been moved from another part of the world due to immigration. Out of two thousand plum varieties in the world, more than 200 varieties are grown in Turkey. In spite of rich genetic source, selection of suitable rootstock is one of the most important problem. There are two types of plant propagation production methods: sexual and vegetative. Grafting, one of the vegetative production method, is widely used in horticultural fruit production. In this method there are two parts, the scion and the rootstock. Rootstocks constitute the subsurface system and influence the phenological, physiological and

economic life of the above ground part of plant. Also, they influence the degree of adaptation of the plant to ecological conditions, such as salinity, pH, drainage, etc. Because of this reason, the use of proper rootstock is a very important issue in fruit farming. The rootstocks obtained by different breeding programs in fruit cultivation are widely used for different purposes. Unfortunately, rootstock breeding research started late in our country. In other countries, the use of plum in rootstock breeding for apricot cultivation is quite common. These rootstocks have been bred for ease of vegetative propagation, dwarfing characteristics and resistance to different climatic and soil conditions. In most rootstock breeding and production studies, cuttings and tissue culture have been the main methods used in vegetative production. Both production methods have advantages and disadvantages. Cuttings which are the classic production practice, are limited to seasonal production periods. In vitro production, on the other hand, can be carried out continuously with appropriate explants and subculture applications. Also, homogenous plant material is obtained by this method. The other advantages of this method are that a large numbers of material can be produced in a short period of time and in a small area.

Bassi and Cossio (1991) reported that genotype plays a significant role in tissue culture regeneration studies, and they emphasized that a successful regeneration protocol in one genotype, may not be successful in another genotype. The most commonly used plum rootstocks in breeding studies are. cerasifera, P. persica, P. insititia and P. domestica. Mariana obtained from breeding by P. cerasifera × P. munsoniana, Myrobolan (P. cerasifera) and Pollizo ve Pixy (P. insititia) and all have different regeneration protocols (Moreno, 2009).

The aims of this study are to determine the best proliferation protocol for the KLDİ-47 plum genotype which belongs to the Prunus divaricataspecie which has the potential to be a rootstock for many stone fruit species.

Materials and methods

This study was carried out at tissue culture laboratory of Horticulture Department of Çukurova University and research field with tissue culture laboratory of East Mediterranean Transitional Zone Agricultural Research of Institute (DAGTEM). The CLDi-47 (*Prunus divaricata*) genotype was used, which is good for vegetative propagation that considering cutting experiment results. Single nodes are taken from fresh shoots of CLDi-47 genotype as initial plant material (Figure 1). The single nodes were kept under the tap water for 30 minutes to remove the phenolic compounds. After keeping at 70 % ethyl alcohol at 20 seconds for surface sterilization, single nodes allowed to stand for 20 minutes in 10 % commercial bleach (0.525 % NaOCl) containing one or two drops of Tween 20. Surface sterilization of single nodes was completed by washing with sterile distilled water 3 times for 5 minutes. All these plant materials were inducted in Murashige and Skoog (MS) as initiation medium for four weeks (Figure 2). After this period of time, they were divided into four groups for evaluating the performance of propagation and vitrification under the different medium. Medium information was given at Table 1. A study carried out by Palaz and Uğur (2018) and reported positive results of another rootstock candidate (SP-2) were used as reference. Three different media containing different combinations of four plant growth regulators were tested.

Figure 1. (A) plant material of CLDi-47 genotype used in this study (B) cutting of single nodes

Figure 2. *In vitro* plants obtained from CLDi-47 genotype

Table 1. Hormonal composition of media used in the proliferation stage

Medium designation	TDZ (mg/l)	NAA (mg/l)	GA_3 (mg/l)	IBA (mg/l)
Medium 1	0.00	0.0	0.0	0.0
Medium 2	0.75	0.5	0.5	0.5
Medium 3	1.5	0.5	0.5	0.5
Medium 4	3.00	1.5	0.5	0.5

1-) Thidiazuron (TDZ), Naphthalene acetic acid (NAA), Gibberellic acid (GA3), Indole-3-butyric acid (IBA).

To determine the performance of the media in terms of regeneration and vitrification, twenty explants were used. Mean of these was taken and evaluated.

Results and discussion

The effect of the different plant growth regulator combinations and concentrations on the propagation and vitrification were given in Table 2. While the first medium was hormone-free MS (30 % sucrose and 8 % agar), the other ones contained different ratios of TDZ, NAA, GA_3 and IBA. The lowest propagation was found in hormone-free medium (Medium 1) with 0.75 value and vitrification was not observed. The highest vitrification (33 %) was recorded in the Medium 2 with 1.21 proliferation rate. The maximum shoot number was obtained from the Medium 3 with 2.26 proliferation rate. This medium was similar to the Medium 2 except the TDZ ratio. Our data showed similarity to results reported by Escalettes and Dosba (1993) and Nowak et al. (2004). Suitable level of TDZ was ranged between 3 μM and 7.5 μM depend on genotypes in their studies.

Table 2. Effect of tested hormonal composition of medium on proliferation capacity and incidence of vitrification

	Medium 1	Medium 2	Medium 3	Medium 4
Proliferation rate	0.75 ± 0.58	1.21 ± 1.58	2.26 ± 2.16	1 ± 0.58
Vitrification (%)	0 ± 0	33 ± 33.68	0 ± 0	18 ± 28.86

Petri and Burgos (2005) reported that there was difficulties in vitro shoot regeneration of the fruit trees. Low success rate was observed using different applications high such as level of auxin, root inducers, subculture and application times performed to increase rooting in commercially important cultivars (Gonzales Padilla et al., 2003; Tian et al., 2007). In our study, it was found that regeneration rate of explants increased in all of medium containing the plant growth regulators when compared with the control medium (Medium 1). Also, the vitrification level was influenced from the concentrations of TDZ and NAA. In an in vitro study carried out by Canlı and Tian (2009) in Japanese plums (Prunus salicina Lind.), a significantly positive correlation was found between TDZ content and shoot regeneration capacity. More number of shoots was obtained in the medium supplemented 9-15 μM TDZ than the medium containing 4.5 μM TDZ.

In a study carried out by Zou (2010), 'Gulf-ruby' plum variety were evaluated in terms of shoot number performance and vitrification rate in the woody plant medium (WPM) containing different combinations of plant growth regulators. The medium supplemented 0.2 mg/l IBA and 2 mg/l BA showed vitrification and severe abnormalities together with slow growth of shoots. The in vitro plants obtained could survive with 67 % success rate after transferring to the greenhouse. In our study, while the vitrification was promoted by low level of TDZ (0.75 mg/l), it was completely inhibited using higher level of TDZ (two fold than first medium). However, vitrification was again observed in Medium 4 containing the highest dose of TZD (3 mg/l). This conflicting can be rooted by highest level of NAA.

Conclusion

As a result of this study, it was clearly observed the effect of the type and concentration of plant growth regulators on the regeneration and vitrification rate on the plum genotype. Especially, TDZ showed great importance in this study. The Medium 3 was the best in terms of the highest regeneration rate and any vitrification symptom. This result is very important for stone fruit cultivation and also for CLDi-47 genotype having rootstock potential.

Abstract

Abiotic and biotic plant stress factors are the major causes of yield limitations. Aluminum toxicity is one of the most important stressors for plant growth and development after salinity. The most common effect of Al toxicity on the plant is the reduction of root growth. Reduced root growth decreases yield and fruit quality. Thus, high-quality rootstocks, that can cope with elevated toxic mineral levels, are important resources for fruit growers and breeders. The CAB-6P (*Prunus cerasus* L.) seedlings were evaluated to determine aluminum toxicity and its effect on biomass production. Seedlings reproduced in tissue culture and grown for 2 months in growth room were used for the study. Plants with similar sizes were transplanted into 9-liter pots filled with turf and perlite medium (2:1). Four doses of aluminum (200-400-600-800 µM) were treated every 30 days one month after transplanting into pots. Above and below ground parts, and leaves were separated after four months of aluminum treatment. Data for root, shoot and leaf biomass (fresh and dry), trunk and root collar diameters, plant height and root length were collected. According to data analysis, there were significant differences between control and elevated doses of Al. Plant height, root length, root and shoot fresh and dry biomass were significantly reduced with increased Al doses. However, trunk (10.88 mm) and root collar diameters (14.74 mm) were larger on 200 µM Al treatment than control (9.90 mm and 12.96 mm, respectively) and other doses. Aluminum doses had a significant negative effect on CAB-6P rootstock growth.

Keywords: *Aluminum toxicity, CAB6-P, Root biomass, Shoot biomass.*

Introduction

Aluminum (Al) is the third most abundant element and the first most abundant metallic element in the earth's crust. A large part of Al is found as complex alumino-silicates, while a small part is found in soluble forms (May and Nordstrom, 1991; Moffat, 1999). Al toxicity is related to pH and is mostly observed on acidic soils (Kochian et al., 2005). Alumino-silicates and aluminum hydroxide minerals dissolve in soil with low pH (under 5.5). Subsequently, Al^{3+} is converted to mononuclear species such as $AlOH^{2+}$, $Al(OH)_2^+$, $Al(OH)_3$ and $Al(OH)_4$ (Kochian, 1995; Ryan et al., 2001; Panda and Matsumoto, 2007). Mononuclear species of Al^{3+} and Al_{13} are the most toxic forms of Al (Kinraide, 1991; Kochian, 1995). However, some other monomeric Al species (like sulphate, phosphate, and silicate Al species) are less harmful. In addition, organic Al-complexes have low toxicity (Schecher and Driscoll, 1987; Schecher and McAvoy, 1992).

It is estimated that 30-50% of arable land in the world is acidic (Jardim, 2007; Panda et al., 2009) and Al toxicity in such soil is one of the main factors limiting the yield (Maron et al., 2008). Al toxicity poses risks mainly for aquatic plants living in acidic fresh waters (Gensemer and Playle, 1999), plants living in forests with acidification risk (Driscoll et al., 2001; de Vries et al., 2007), and crops grown in acidic tropical soils (Baligar and Fageria, 1997). Even though Al toxicity is a serious issue worldwide, our knowledge of Al chemistry

is still limited because of its extremely complex nature. A large spectrum of polynuclear inorganic and organometallic complexes of strongly varying stability in soil and water is the reason for this complexity (Kinraide, 2003; Poschenrieder et al., 2008).

Although the primary target of Al toxicity on the plant is not yet known (apoplastic or symplastic) (Taylor, 1995; Matsumoto, 2000), the literature suggests that Aluminum leads to primary damage in the apoplasts of peripheral stem cells. These structures participate in important processes such as cell wall assembly, ion flow, and structural properties of the plasma membrane (Hecht-Buchholz and Foy, 1981; Horst, 1995; Kochian, 1995; Rengel, 1996). Additionally, a possible symplastic target of Al, such as the root cytoskeletal structures, (Barlow and Baluska, 2000) is the direct binding to the meristematic stem cell nucleus (Foy et al., 1978; Silva et al., 2000). Al binds directly to the microtubules found in the nuclei of these cells, resulting in dysfunction (Blancaflor et al., 1998; Sivaguru et al., 1999a, 1999b). Growth inhibition is widely used in the assessment of Al toxicity. Root/shoot ratio, total root and shoot lengths and surface area reduction are commonly used parameters (Clarkson, 1969; Alam, 1981; Fagria, 1982; Pavan and Bingham, 1982a; Kochian, 1995; Moustakas et al., 1996; Blancaflor et al., 1998; Ramachandran et al., 2000; Barcelo and Poschenrieder, 2002; Zobel et al., 2007; Azmat and Hasan, 2008). At the same time, the parts of the plant which are affected by Al are mostly roots. The most sensitive region of the root against Al toxicity is the transition zone. This zone is located between active cell division and fast cell elongation zones (Sivaguru and Horst, 1998). The reason for this sensitivity is that it is the place where the elements necessary for rapid elongation are prepared (Verbelen et al., 2006). The Al damages the active cell division zone and neutralizes other factors that cause root growth (Doncheva et al., 2005).

Al toxicity creates a root system with many short and fragile lateral roots (Ryan et al., 1993; Doncheva et al., 2005). As these roots are reduced in length, their thickness increases (Blancaflor et al., 1998; Ramachandran et al., 2000; Zobel et al., 2007). The shoots and leaves of plants start to become damaged due to imbalances in water and nutrient uptakes resulting from root damage (Moustakas et al., 1996). According to some studies, Al reduces biomass in the above-ground parts (Azmat and Hasan, 2008), increases thickness in cell wall (Konarska, 2010), increases lipid peroxidation (Zhang et al., 2007), causes nutritional imbalances (Guo et al., 2007), changes in the photosynthetic performance (Jiang et al., 2008), and changes in the amount of chlorophyll (Chen et al., 2005; Zhang et al., 2007; Azmat and Hasan, 2008; Jiang et al., 2008). It has also been reported that Al toxicity reduces CO_2 assimilation (Moustakas et al., 1996; Lidon et al., 1999) and causes photosystem damage (Zhang et al., 2007; Reyes-Diaz et al., 2010) in several species.

The aim of this study was to examine the effects of 4 different Al doses on some morphological characteristics of CAB-6P (*Prunus cerasus* L.) clonal rootstock.

Material and Methods

The study was carried out in the growth room and greenhouses of the Department of Horticulture, Faculty of Agriculture of the Selçuk University (Turkey) in 2016. Aluminum has been treated to each plant once a month for 4 months starting by June 25th, 2016. The study was planned according to randomized complete blocks design with 3 replications with one plant per replication. The treatments were; 0 µM, 200 µM, 400 µM, 600 µM, and 800 µM doses of Al. Plants produced with seeds were kept in a 2-liter pot at a temperature of 27,5^{o}C / 22,5^{o}C (day/night) and 14/10 h (day/night) day length in a growth chamber until a certain plant height (50 cm) was reached. A mixture of peat/perlite (2/1 v/v) was used as growing medium. When plants reached 50 cm in height, they were transferred to the greenhouse in 9-liter pots (same growth medium) and all necessary cultural processes were carried out during the study. As of November, the plants removed, plant trunk diameter (5 cm above ground),

root collar diameter (just above first lateral root), plant height (from ground to top), root length (from root collar to tip of root), stem fresh and dry weights, root fresh and dry weights (from root collar), and leaf fresh and dry weights were investigated. The data obtained were assessed at $p \leq 0.05$ significance level with the IBM SPSS v.20 (IBM Corp. IBM SPSS Statistics for Windows, Armonk, NY) statistical software with one-way variance analysis (ANOVA) and subjected to Duncan Multiple Comparison Test.

Results and Discussion

Trunk diameters (TD) of the plants were measured with digital caliper 50 days after the last treatment of Al. Statistically significant differences were found ($p \leq 0.05$) and Al treatments thickened the plant trunk. In particular, 200 µM (10.88 mm) and 600 µM (10.80 mm) Al treatments provided the formation of thicker tree trunks than the control (9.90 mm). While TD was same in 400 µM Al treatment and control, 800 µM Al treatment (9.61 mm) decreased TD compared to control. The reason for this seems to be the limited plant growth because of high Al toxicity. Some previous studies reported that Al has positive effects on plant growth. According to Ghanati et al. (2005), root lengths of tea plants grown in nutrient solution with 500 µM Al (pH 4.3) were 2.5 times longer than the control (). Similarly, Al treatments had positive effects on root activity, stem cell lengths and relative dry weight in *Melastoma malabathricum*. However, in the same study, Al treatments caused toxic effects on barley (*Hordeum vulgare*) (Watanabe et al., 2005). In another study, *Quercus serrata* seedling traits such as shoot dry weight, root dry weight, length of newly grown roots, relative height, and number of branched roots were found to be higher than control and low pH (-Al) treatments in 2500 µM Al treated plants (Tomioka et al., 2005). When the results of the above studies are compared with this study, the TD value is expected to increase with low Al doses. However, while other characteristics are negatively affected by increased Al doses, the elevation of TD in the 600 µM Al dose cannot be explained by this approach. This may be due to the positive response of plants growing during the first few months under low Al doses. The growth of plants may have slowed down as they were exposed to more Al in 3rd and 4th month.

Table 1. Effect of aluminum treatments on trunk diameter (TD), root collar diameter (RCD), plant height (PH) and root length (RL).

Al Doses	TD (mm)	RCD (mm)	PH (cm)	RL (cm)
0 µM	9.90^{bc}	12.96^{b}	80.67^{a}	35.50^{a}
200 µM	10.88^{a}	14.74^{a}	77.00^{b}	33.33^{b}
400 µM	9.90^{bc}	12.25^{bc}	74.67^{c}	31.00^{c}
600 µM	10.80^{ab}	11.64^{c}	72.67^{d}	29.00^{d}
800 µM	9.61^{c}	11.60^{c}	68.33^{e}	28.50^{d}
LSD	2.31	0.77	1.35	1.32
P value	0,042	0,000	0,000	0,000

The RCD results determined by measuring with caliper, immediately after the plants were removed, were statistically significant ($p \leq 0.05$). The RCD increased with 200 µM Al treatment (14.74 mm) compared to control plants (12.96 mm), while RCD began to decrease from 400 µM Al treatment (12.25 mm) (Table 1). The RCD was significantly reduced in 600 µM (11.64 mm) and 800 µM (11.60 mm) Al treatments. The RCD values obtained from this study were similar to previous studies in which Al effects plant growth. It has been reported in several studies that low Al doses affected plant growth positively and Al has contributed to the growth of plants (Schier, 1985; Ghanati et al., 2005; Tomioka et al., 2005; Watanabe et al., 2005). However, the studies that indicate root damage as plants exposed to higher Al concentrations are quite extensive (Foy, 1983; Schier, 1985; Ryan et al., 1993; Mossor-

Pietraszewska et al., 1997; Blancaflor et al., 1998; Ramachandran et al., 2000; Doncheva et al., 2005; Zobet et al., 2007). High Al concentrations used in this study resulted in similar results with previous studies, and the RCD values decreased as the treated dose increased.

The plant heights were measured from the ground level to apical meristem with a metric measure before the plants removed. The plant height (PH) results obtained from the current study was statistically significant ($p \leq 0.05$). The longest plants were obtained from the control (80.67 cm) (Table 1). Plants began to shorten in length (200 µM, 77.00 cm) and the plant height continued to decrease (800 µM, 68.33 cm) as the Al concentration increased and the shortest plants were obtained from 800 µM Al. These results do not coincide with studies reporting that low Al doses affect plant growth positively (Ghanati et al., 2005; Tomioka et al., 2005; Watanabe et al., 2005). However, the difference between control and the lowest Al dose (200 µM) was not very large. On the other hand, there have not been many studies investigating the effect of high Al doses on PH. In a study conducted with Boron (B) and Al by Riaz et al. (2018), Al (400 µM) treated plants were shorter compared to the control. In this study, the plant length was shortened with the increased Al doses. However, plants treated with B (10 µM) and Al (400 µM) were taller compared to the control. In addition, studies on *Oryza sativa* (Fagria, 1982), *Coffea arabica* (Pavan and Bingham, 1982a, 1982b), *Manihot esculenta* (De Carvalho and Cesar, 1984), and Gleditsia species (Thornton et al., 1986b, 1986c) have shown that the height of shoots is reduced with Al treatments.

After the plants removed, the length from the root collar to the tip of the main root was measured with a metering device. The results obtained were evaluated and found statistically significant ($p \leq 0.05$). According to the results, the effect of Al doses on the root length was negative. It can be seen that root length starts to decrease with the 200 µM Al (33.33 cm) treatment and the root length decrease with higher Al doses are continued (Table 1). In plants treated with 800 µM Al (28.50 cm), root length was considerably shorter than control (35.50 cm). In many studies, roots of plants exposed to toxic Al doses are shortened (Foy et al., 1978; Ryan et al., 1993; Mossor-Pietraszewska et al., 1997; Ramachandran et al., 2000; Doncheva et al., 2005; Zobel et al., 2007). Similar results were obtained from this study, and as Al doses increased, plant root lengths were reduced. Some researchers reported that roots extend to soil zones where Al is lower by orienting lateral roots (Foy, 1984; Barcelo and Poschenrieder, 1990; Ryan et al., 1993; Doncheva et al., 2005). However, since this study was carried out in pots, there was no soil part with low Al dose where the roots could be oriented, and therefore the root weight decreased with the dose increase, as can be seen in table 2.

Table 2. Effect of aluminum treatments on above ground fresh mass (AGFM), above ground dry mass (AGDM), root fresh mass (RFM) and root dry mass (RDM).

Al Doses	AGFM (g)	AGDM (g)	RFM (g)	RDM (g)
0 µM	84.22^{a}	30.90^{a}	153.61^{a}	48.45^{a}
200 µM	60.18^{b}	28.87^{b}	111.54^{b}	37.54^{b}
400 µM	56.98^{b}	27.12^{c}	105.78^{c}	37.11^{b}
600 µM	51.22^{c}	24.16^{d}	102.13^{cd}	36.70^{b}
800 µM	45.75^{d}	23.58^{d}	98.67^{d}	36.43^{b}
LSD	4.33	1.22	4.60	1.98
P value	0.000	0.000	0.000	0.000

After the treatments were completed and the plants were removed, the fresh and dry weights of the above ground parts were determined by weighing. The results were evaluated and statistically significant differences were found ($p \leq 0.05$). The AGFM (84.22 g) and AGDM (30.90 g) of control were higher than all Al treatments. However, while AGFM of plants treated with 200 µM Al (60.18 g) decreased more than 25% compared to the control, AGDM

(28.87 g) decreased at a lower rate. Similarly, the reduction rates in AGFM (45.75 g) and AGDM (23.58 g) were different in 800 µM Al treatment. It is understood that Al treatments affect AGFM more than AGDM (Table 2). Earlier studies suggested different views on the effect of Al on shoots and leaves. There are studies show that shoots and leaves are as sensitive as roots against Al toxicity, but that damage starts from the roots first (Thornton et al., 1986b; Thornton, 1986c). However, Foy (1983) states that Al toxicity does not lead to any considerable damage on shoots when visible damage was observed in the roots. Schier (1985) reports that serious damage to the roots of *Picea rubes* and *Abies balsamea* species occurs without any symptoms except slow growth in shoots. However, majority of the studies reports that Al toxicity damages shoots and leaves at various levels (Rees and Sidrak, 1961; Awad et al., 1976; Alam, 1981; Hutchinson et al., 1986; Pegtel, 1986; Foy, 1996; Azmat and Hasan, 2008). Unlike above studies, Krizek et al. (1997) reported that shoots react more rapidly to elevated Al doses than roots and begins to be affected by lower Al doses. In the current study, , it was understood that Al toxicity damages the shoots as well as roots (Tables 1, 2 and 3). Even though short-term and low-dose treatments may not affect shoots as mentioned, plants in this study were exposed to different doses of Al for 4 months, and the height, fresh and dry weights of shoots were affected as much as roots from Al toxicity.

After the plants were removed, fresh and dry weights of the roots which cut from the root collar were weighed with a precision scale. The differences between the treatments were found to be statistically significant ($p \leq 0.05$). Fresh and dry weights of roots decreased from 200 µM Al treatment due to increased Al dose. 200 µM Al treatment reduced RFM (111.54 g) compared to control (153.61 g) by approximately 25%, the RDW (37.54 g) was reduced by approximately 22% compared to the control (48.45 g) (Table 2). At 800 µM Al treatment, RDM (36.43 g) decreased by about 25% while RFM (98.67 g) decreased by approximately 36%. The proportion of the decrease in RFM was higher, which can be explained by the decrease in water uptake due to damaged roots. While well-developed roots of control plants can take up high amounts of water and water-soluble minerals, the weak roots of Al-treated plants cannot achieve this. The results obtained from the present study are similar to previous studies on Al toxicity. In some studies, Al toxicity reported reducing root length (Foy, 1983; Mossor-Pietraszewska et al., 1997), fresh (Watanabe and Osaki, 2002) and dry (Fagria, 1982; Foy, 1996) weights by damaging the roots. Al reduced root fresh and dry weights in *Oryza sativa* (Fagria, 1982), *Picea abies, Betula pendula* and *Pinus sylvestris* (Eldhuset et al., 1985), *Picea rubens* and *Abies balsamea* (Schier, 1985), *Gleditsia triacanthos* (Thornton et al., 1986b) and *Secale cereale* (Silva et al., 2012), depending on the dose. The decrease in the root fresh and dry weights of plants as the treated Al doses increased indicates that this study is similar to previous studies.

Table 3. Effect of Aluminum treatments on leaf fresh mass (LFM) and leaf dry mass (LDM).

Al Doses	LFM (g)	LDM (g)
0 µM	21.76[a]	7.15[a]
200 µM	17.00[b]	6.09[b]
400 µM	15.20[c]	5.97[b]
600 µM	11.84[d]	4.36[c]
800 µM	11.39[d]	4.42[c]
LSD	1.80	0.23
P value	0.000	0.000

After the plants were removed, leaves were separated and weighed as fresh and dry. Results were evaluated and found statistically significant ($p \leq 0.05$). Al treatments reduced leaf fresh mass (LFM) and leaf dry mass (LDM) (Table 3). The LFM and LDM continued to decrease

as the Al dose increased. However, LDM (4.42 g) of plants treated with 800 µM Al was higher than LDM (4.36 g) of plants treated with 600 µM Al dose. However, both results were still in the same statistical group. The LFM of the same doses (600 µM and 800 µM) are in the same group and their values were 11.84 g and 11.39 g, respectively. In addition, LDM decreased at a relatively low rate (control: 7.15 g, 200 µM Al: 6.09 g) while 200 µM Al treatment (17.00 g) decreased LFM at a higher rate compared to control (21.76 g). These results in above ground mass (AGM) and root mass (RM) may be related to water and nutrients uptake. According to previous studies, leaves are affected by Al toxicity and the leaf weight is decreased (by dose increase). Al toxicity reduced leaf initiation in *Gleditsia triacanthos* (Thornton et al., 1986a), leaf number, surface area and leaf dry weight in *Medicago sativa* (Dessureaux, 1969), and reduced leaf initiation due to the decreased shoot extension in *Picea abies*, *Betula pendula* and *Pinus sylvestris* (Eldhuset et al., 1985). Accordingly, the current study is consistent with previous studies and Al toxicity has adverse effects on the leaves.

Conclusion

Al toxicity is a potential threat for plants in acidic soils. Agricultural production can be restricted as a result of excessive Al in soils with low pH values. However, as noted above, lower doses of Al may positively affect the growth and development of some plant species. Increased Al concentration and decreased pH causes damage and decreased crop production and profit.

Researchers seem to agree that there are two methods of control on Al toxicity. These methods are tolerance to Al toxicity (tolerance mechanisms may differ according to species) and removal of Al from the root zone. However, the most emphasized subject seems to be to determine the tolerant species and cultivars. In future studies, fruit species and cultivars with tolerance to Al and can grow in acidic soil should be determined and acidic agricultural soils with high Al content should be opened to economic production.

Abstract

Cowpea is an important legume that is resistant to arid conditions and rich biomass. This study was carried out to determine the relationship between the seed yield, biologic yield and leaf properties. The experiments were conducted at two locations where one of them was warm (Samsun), other was with continental climate (Amasya). Sixteen cowpea line/cultivars were used in this study. The experiments were set up in the randomized complete block design with three replications. In the both locations, sowing on seeds was made with 60 cm row space to plots 12 m^2. The leaf samples were collected for both locations in a period at the beginning of pod setting period. All of leaf properties were determined by LICOR LI 3000A Portable Leaf Area Meter. Collected data were subjected to variance analysis in MSTATC package program by being combined over the location. According of variance analyses, total leaf area of plant, number of leaves, leaflet length, dry matter rate of leaf, seed yield per plant and biological yield showed statistical difference among genotypes. The significant differences between two locations were found for biological yield, seed yield and number of leaves. Plant seed yield and biological yield positively and significantly correlated with leaves number, leaf area per plant, leaflet number, leaflet area of per plant.

Key words: *cowpea, leaf properties, seed yield.*

Introduction

Water demand globally is projected to increase by 55% between 2000 and 2050. Much of the demand is used by agriculture, which accounts for 70% of global freshwater (URL-1). And in many places where large-scale irrigated agriculture takes place, demand is already outstripping supply. The regions at highest risk for future water stress are clustered around these areas: the Mediterranean, the Middle East, Western North America, Eastern Australia, Western Asia, Northern China, and Chile (URL-2).

Located in the Mediterranean basin, Turkey is a country where many cool and warm season legumes are grown. Beans grown in almost every part of Turkey and is a plant lovingly consumed. Our region is one of the major bean growing areas of Turkey. The seasonal water consumption of bean was measured as 732 mm (Şehirali ve ark.,2005). One of the factors limiting the growth of bean is the high water consumption while the other high temperatures. The cowpea is similar to bean plant as a morphological features and usage shape. It has been found that in many parts of the world the cowpea is more tolerant to warmth and constancy than other legume plants (Sing et al. 1997; Hall et al. 2003, 2004). Due to these characteristics, cowpea is a remarkable plant in terms of the areas where beans are grown in our country (Çulha ve Bozoğlu, 2016). Cowpea is mostly grown in the Aegean, Mediterranean and South-Eastern Anatolia in our country and in restricted areas in our region. (Çulha ve Bozoğlu, 2017).

Cowpea is consumed in the form of food similar to beans. And also it is a very high plant with a potential for feed (Genckan 2003). There is potential in tropical regions to include cowpea (*Vigna unguiculata* (L.) Walp.) in rice (*Oryza sativa*) based cropping systems, especially

during the post-monsoonal dry season (Timsina et al. 1994). Acoording to Umar and et al.(2010) the leaves, stems and seeds of cowpea have antimicrobial properties that frequent consumers had lower blood pressures and total serum cholesterol levels. Consequently, consumers were less likely to be diagnosed with high Blood Pressure, diabetes and other heart diseases. Based on this information, studies are being carried out for the spread a long time in our region. Up to now, studies have shown that the cowpea is adapted to the conditions of the region. In experiments conducted under Samsun conditions, seed yield of cowpea is about 129-169 kg in genotypes and the results shown that it is possible to grow without irrigation except extremes years. (Gülümser ve ark., 1989; Bozoğlu ve Gülümser, 1995). It has been seen that the genotypes used in the adaptation studies for the development of the suitable varieties for the region brought plenty of vegetative biomass. Accordingly, this study was carried out in order to determine whether these properties could be the criterion of choice for the varieties to be developed for dry seed by establishing the relationship between leaf properties and seed yield.

Material and Method

Materials of this trial were 14 lines selected with invidual plant selection from population were collected different regions of Turkey and 2 registered varieties (Karagöz, Akkız). The testa color of B_7 and B_{11} are red, other genotyes were white. Hilum color of white color seed at B_9, B_{10}, B_{13} are brown, B_{14} is white and other are black.

The experiments were carried out two locations (Samsun (S), Amasya (A)) that were selected for representation of Middle Black Sea Region. First location (S) represents costal area of region, second (A) the interior of region. Some climate data of these locations can be sown at the figure 1.

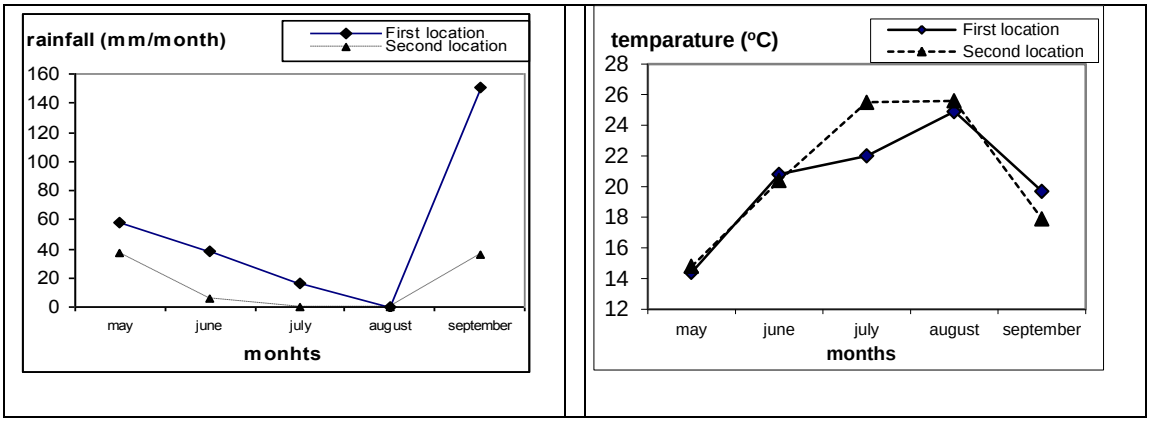

Figure 1. Some climate data of experiment areas

The trial soil of Samsun (first location) has clay, neutral ph, unsalty, middle organic material and unlime soil type, Amasya (second location) area has an average altitude of 450 m from the sea, has clay loam, alkaline ph, lightly salty, middle organic material, calcic soil type. Sowing were done on the last week of May both locations. Row spacing was 60 cm, with 15 cm between plants and five rows per plot. The trial was fertilized at the emergence time of plant with nitrogen fertilizer that was set total 4 kg per decare. Irrigation were three times in both locations. The leaf samples have been collected for both locations in a period which are beginning of pod filling period. Number of leaves, total leaf area per plant, leaflet length, leaflet with, dry leaf weight per plant, dry matter of leaf rate were determined. Leaf measurements were done with LICOR LI 3000A Portable Area Meter. Jesus et al.(2001) reported that, the LAI-2000 can be used to estimate the LAI of common bean.

All of data were transformed with square root. After than analysis of variance using the MSTATC program was performed after data was combined over the locations. Mean separation was done Duncan's multiple range test. Correlation analysis was applied in order to determine the relationships between the properties

Result and Discussion

In the study carried out with 16 cowpea genotypes at two different locations, the variance analysis showed that number of leaves, leaf area, leaf length, dry leaf weight, seed yield and biological yield statistically effected by genotypes (Table 1); leaf number and leaf dry weight by the locations (Figure 2).

The number of leaves in different genotypes varied between 11.8-37.3. The genotype with the highest number of leaves and the seeds with the lowest number of leaves were found to have the same seed and hilum colors (black). The number of leaves was found to be positively and significantly related to leaf area and dry leaf weight and leaf dry matter ratio (Table 2). Jose et al., (2003) founded that LAI reached its maximum value at the flowering and pod-filling stages. The leaf area determined in the pod filling cycle varied between 8.64-20.04 dm^2 in the genotypes used. Akinyomi et al., (2003) determined for different the tillage systems ranged between 34 and 45, with a mean of 38 leaves and 23 and 27 with a mean of 25 cm^2 leaf area. It was determined that the genotypes in our study were more variable in leaf count and leaf area was higher.

The statistical effect of locations on leaf number and area is not affected. However, less leaf area was obtained in Amasya (Figure 2). While the Samsun location received a precipitation of approximately 262 mm during the growing season, the amount of precipitation in Amasya was 79 mm in the same period. There was no significant difference in temperatures except for the August average (Figure 1). In addition to the irrigation, the vegetation period was extended in Samsun, which is more than one month. As the period elapsed, both the biological yield and the seed yield became higher due to this. The correlation analysis showed no significant relationship between leaf yield and other leaf characteristics except leaf dry matter ratio and biological yield (Figure 2).San Jose et al (2003), reported that the leaf area index was similar in varieties (2.13 and 2.15m^2) in the maximum growth period when they compared the energy changes during growth on the two cowpea varieties.

The cowpea leaf consists of 3 leaves. In the measurements, each leaf was measured and the width and length were determined by taking the average of all of them. In general, the terminal leaves are longer and the lateral leaves are wider. It has been determined that the leaf length of the genotypes used is statistically influenced by varieties. Leaf length ranged from 7.2 to 12.5 cm and width varied from 2.3 to 4.6 cm. The shortest leaf was seen in Karagöz variety which has black hilum coloring. Genotypes differing in seed and hilum color were found to be in the same statistical group in terms of length.

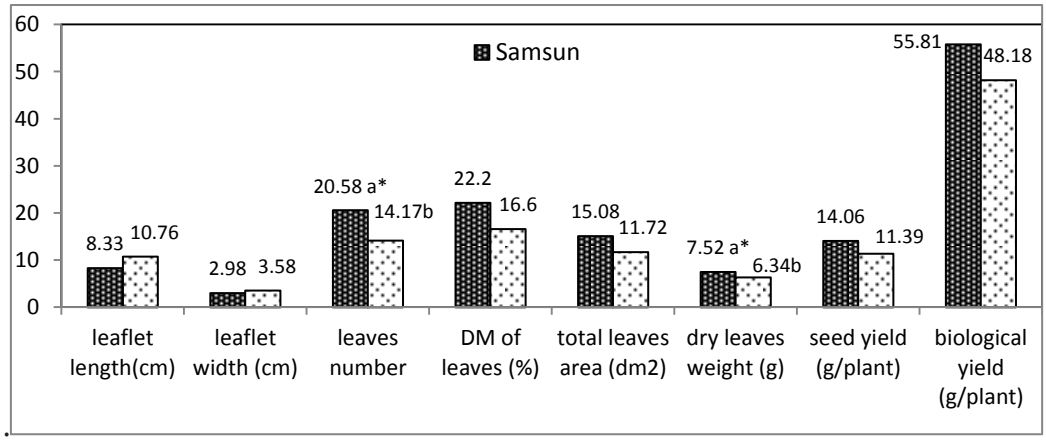

Figure 2 : Means for two locations some leaf characters, seed and biological yield of cowpea

Significant and negative relationships were determined by leaf length, dry leaf weight, dry matter content and seed yield (Figure 2). The seedlings have fallen as the leaves grow longer. Anyia and Herzog (2004) reported that some species of genotypes could be protected from drought by shrinking the leaf area and reducing the leaf area and gas permeability, resulting in a decrease of 11-40% in biomass across the genotypes. Reductions in biomass were due to decline in leaf gas exchange and leaf area during water deficit. Cowpea is a plant that can grow vegetative parts in excess amount and prolong the vegetative development when the temperature is not too high like our region. For these reasons, the vegetative cycle is prolonged and the pod setting is delayed, and the vegetation period of the region is not long enough, so there is not enough time for pod filling and the yield is low. Bozoğlu et.al.,(2016) reported that in these varieties, the harvest period was different statistically in the genotypes in the studies conducted at 2 years and 2 locations.

Table 2. Simple linear correlations among some leaf characteristics and seed and biological yield per plant

	Leaves number	Leaf area	Leaflet lenght	Leaflet width	Dry leaves weight	Dry matter of leaves	Seed yield

Biological yield	0.261	0.497**	-0.122	0.065	0.251	0.293	0.575**

Conclusion

Turkey is not a cowpea plant origin center. It is cultivated in small areas in our country and mostly fresh fruit and dry seeds are used as food. However, in recent years, the value of the feed has also been understood, and it is especially regarded as silage cultivated with maize. As the researches increase, the different uses of the plant are also diversified. Especially, the fact that bringing vegetative parts to the ladies in a large amount reveals the idea that these evenings can be evaluated in different forms. There are some research about the inhibitory effect of cowpea leaf extracts on the growth of bacterial and fungal pathogens. In recent

years, some studies are being carried out for the widespread cultivation in our region. For this reason, we are trying to learn every properties want to learn very components of cowpea.
In this study, it was aimed to reveal the relations between leaf and leaf properties, which are the most important organs. There were no significant relationships between leaf yields (number of leaves, leaf area, leaflet length, leaf width, dry leaf weight) and seed yields examined in the study conducted with 16 different genotypes at two locations. It was concluded that there is a positive relationship between seed yield and biological yield and leaf dry matter content. This suggests that it is important for us to select the appropriate genotypes for the planting period and the growing period, especially considering the regional conditions. Cowpea is one of the brightest plants for the future in some regions where climate change and risk of drought.

Abstract

In addition to the good adaptation of high temperature and low nutrient soil, cowpea (*Vigna unguiculata* L.) can be a good source of forage for livestock. This research was conducted to determine forage yield and some quality parameters of cowpea grown as double crop in Samsun ecological conditions. In this study, we examined hay and seed yields and related traits of cowpea grown as double crop with different row spaces. In the experiment, two types of forage cowpea genetics Registered Cultivar Ülkem and genotype black seed cowpea and four different row spaces were used (20cm, 35cm, 50cm, 65cm). Field trials were designed in randomized block design with three replications and 8 rows in each plot. Cowpea seeds were sown after wheat harvesting at July 13, 2017. The first cut was after 57 days (8 Sep) and the second cut was made after 90 days (10 October). Hay yield of the first cut was higher than the second one. Other than the hay yield, plant height, stem diameter, crude protein, ADF, and NDF were also determined. Field results showed that the hay yield ranged from 3.98 to 7.12 ton ha-1 for the first cut and 0.72 – 1.46 ton ha-1 for the second cut. Plant height in the first cut was between 111.2 – 137.3 cm were height of the second cut, they were 24.0 – 29.6 cm. Plant stem diameter was between 6.10 - 8.77 mm. At the laboratory work, it was clarified that crude protein ratios of hay were 18.87 – 21.14% for the first cut and 24.7 – 27.65% for the second cut. ADF ratios were 25.95% - 28.00% in first cut, while the second cut was 19.13 - 24.24%. NDF ratios of hay were ranged from 33.66 to 36.64% and from 24.48 to 31.15% for the first and second cuts respectively.

Keywords: *Cowpea, Forage yield, Row space, Second crop*

Introduction

The cowpea (*Vigna unguiculata* L.) is an important legume widely cultivated in tropics and subtropics for forage, green pods and grains (Ali et al., 2004). Cowpea is usually better adapted to drought, high temperatures and other biotic stresses compared with other crops (Kuykendall et al., 2000; Martins et al., 2003). However, growth and development of many cowpea cultivars are affected by drought and high temperatures, especially during floral development (Dadson et al., 2005).

The biggest technical constraint in livestock production in Turkey is forage deficiency especially during summer period when pasture vegetation is dry. So there is a need for new warm-season forages to fill forage gap in this period. In general, solutions to forage shortages during the summer months have included the use of perennial and annual warm-season species for pastures, hay or silage. Forage cowpea is generally grows between 30-120 cm (Davis et al., 1991; Ismail and Hall, 2000; Worku, 2018) row distance. Ülkem is first registered forage cowpea cultivar of Turkey That it has lots of leaf and high biomass yield.

Cowpea hay is a nutritious balanced fodder for animals (Singh et al., 2003) and has a great function in feeding animals. Having a high nutritive value of green forage cowpea, hay contains 14-21% crude protein, while the seeds have the rate of 18-26% crude protein. It was stated that cowpea is grown alone for forage yield. However, it could be grown mixed with maize, sorghum and millets for silage (Ismail and Hall, 2000; Saricicek et al., 2002; Bilgili,

2009; Basaran et al., 2011; Ayan et al. , 2012). Cowpea can be grown as the main crop or double crop for the aim of forage production in agricultural system in Turkey. Especially in coastal area of Turkey like Black Sea Region that has a very mild climatic conditions, cowpea can be easily grown as double crop after winter cool season cereals.
The aim of this study is to determine the forage yield and some agricultural traits of cowpea grown as double crop with different row spacings in ecological conditions of Samsun.

Materials and methods

The study was carried out in 2017 and was designed as factorial design at randomized blocks with 3 replicates in Samsun (Turkey) ecological conditions. In the experiment, it was used two types of forage cowpea genetics Registered Ülkem and genotype black seed cowpea with four different row space were used (20 cm, 35 cm, 50 cm, 65cm). The experimental plots consisted of 8 rows and 5 m length. Throughout the vegetation period (from July to October) of 2017 total rainfall were 77.5 mm, mean temperature was 22.1 0C, average relative humidity was 63.68 %. The texture experimental area was clay (56.3), organic matter was medium (2.68), nötr (6.89), P_2O_5 content good (22.89 kg/da) and without salt (0.52). At the experiment, it was sowed after harvesting wheat crop exactly 13 July while we have made first forage cut after 57 days (8 Sep) and the second cut was made after 100 days (20 October). In the study hay yield, plant height and stem diameter were measured, while crude protein, ADF, and NDF were examined in the laboratory. Crude protein, acid detergent fiber (ADF), neutral detergent fiber (NDF contents of samples were determined by using near infrared reflectance spectroscopy (NIRS) 13-15. With software program coded IC-0904FE.
The study was completed in irrigated conditions nine times. Irrigation process was continued until soil humidity comes to field capacity. All data obtained from this study was analyzed by using SPSS 17.0 program. The differences amongst the mean values were calculated according to DUNCAN test.

Results and discussion

Plant Height and Stem Diameter

The results about plant height and stem diameter obtained from cowpea genotypes grown as double crop with different row spacings are given in Table 1. Plant height values of cowpea was varied between 137.27 and 111.20 cm, but there was no statistically difference between genotypes and row spacings. Some researchers declared plant height of main crop cowpea as follows; Gülümser et al. (1989) as 74 - 136 cm in Samsun Conditions, Akdağ et al. (1998) as 50.33 – 75.49 cm, Ceylan and Sepetoğlu (1999) as 52.30 – 161.30 cm, Büyükkılıç (1995) as 116 -122 cm. The highest plant height was determined as 29.60 cm for Ülkem cultivar grown with 20 cm row spacing in the second cutting. But plant height of the treatments were the same statistical group except for Ülkem cultivar grown with 20 and 35 cm row spacings. There was no difference between the genotypes (Table 1).

Table 1. Plant height and stem diameter values of cowpea grown as double crop with different row spacings (cm)*

Cultivar/ Genotip	Row Spacing (cm)	Plant Height (cm)		Stem Diameter (mm)
		1. cutting	2. cutting	
Ülkem	**20**	131.80	23,96 **c**	6.59 **b**
	35	137.27	25,46 **bc**	7.58 **ab**
	50	133.07	26,13 **ac**	6.82 **ab**
	65	129.47	27,47 **ab**	7.84 **ab**
Ortalama		**132.90 A**	**25.76 B**	**7.20**
Genotip	**20**	132.87	29,60 **a**	6.10 **b**
	35	111.20	26,76 **ac**	7.33 **ab**
	50	119.00	27,03 **ac**	7.32 **ab**
	65	131.93	28,38 **ab**	8.77 **a**
		123.75 B	**27.94 A**	**7.38**

*There is no difference (P≤0.05) amongst the values indicated same letters within the same column.

Average stem diameter was 7.20 mm in Ülkem cultivar and 7.38 mm in Genotype. Increasing row spacing caused increasing stem diameter as well. The stem diameter of Ülkem was lower than the stem diameters of the genotype (Table 1). Stem diameter of cowpea was found as 8.80 – 8.58 mm by Ayan et al. (2011) in Samsun conditions and 5.9 – 10.8 mm by Ünlü (2014)in İsparta conditions.

Hay Yield

The results about hay yield obtained from cowpea genotypes grown as double crop with different row spacings can be seen in Table 2.

Table 2. Hay yield values of cowpea grown as double crop with different row spacing (kg ha^{-1})*

Cultivar/ Genotip	Row Spacing (cm)	Hay Yield (kg ha $^{-1}$)		Total Hay Yield (kg ha -1)

*There is no difference (P≤0.05) amongst the values indicated same letters within the same column.

The highest hay yield was obtained from Ülkem cultivar with 20 cm row spacing (7123.8 kh ha^{-1}) but hay yield of genotype with 20 cm row spacing was in highest group. Hay yield was decreased as the row spacing increased. It can be attributed to that increased in parallel to increase of number of plant per square meter. The genotype gave higher hay yield compared to cultivar. In the second cut, hay yield of the whole treatments were in the highest group except for Ülkem cultivar with 20 cm row spacing. Regrowth of the cowpea plants was after 8th of September, thus growth and difference were limited.
When we look at the total hay yield, the highest values were obtained from both genotype and Ülkem cultivar grown with 20 cm row spacing (8011.6 and 7844.3 kg ha^{-1}, respectively).
The lowest hay yield was determined for Ülkem cultivar with 50 cm. Some previous researchers revealed the hay yield of cowpea as follows; Ayan et al. (2017) 9.78 – 15.87 t ha^{-1}, Ayan et al. (2011) 5860 – 8760 kg ha^{-1}, Atış and Yılmaz (2005) 4580 – 6390 kg ha^{-1}, Boz (2006) 1480 – 4760 kg ha^{-1}, Jatasra et al. (1989) 3980 – 4730 kg ha^{-1}.

Crude Protein, ADF and NDF ratios of Hay
The values about crude protein, ADF and NDF contents of cowpea hay are given in Table 3.

Table 3. Crude Protein, ADF and NDF contents of cowpea hay (%)*

Cultivar/ Genotip	Row Spacing (cm)	Crude Protein		ADF		NDF	
		1. cutting	2. cutting	1. cutting	2. cutting	1. cutting	2. cutting

	65	19.94	24.70	26.55	20.05	35.04	25,48ab
		19.82	**26.49**	**26.33**	**21.13**	**34.44**	**26.60**

*There is no difference (P≤0.05) amongst the values indicated same letters within the same column.

There were no statistical differences between treatments in terms of crude protein content of cowpea hay in both cutting. Crude protein content of cowpea hay ranged from 21.14% to 18.87% in the first cutting. Crude protein ratio values varied between 27.65% and 24.70% in the second cutting. The second cut was made earlier development stage of cowpea plants. Thus crude protein ratios were higher compared to the first cutting values (Table 3).
Cowpea fodder is a rich source of crude protein up to 184 g kg-1 (Khan et al., 2010). Ayan et al. (2012) nine Cowpea (Vigna unguiculata L. Walp) genotypes were assessed for forage yield and quality features during 2005 and 2006 summer growing season at two locations (Samsun and Kavak) in Turkey. Researchers were found the crude protein content of cowpea hay in ranged from 193.4 to 147.0 g kg-1.
Ayan et al. (2017) were determined the crude protein ratios of hay between 18.61% and 20.00% in ecological condition of Suluova. There were no significant differences among genotypes for ADF contents in both cutting (Table 3).

ADF contents of hay were 25.95 – 28.00% in the first cutting and 19.24 – 24.24% in the second cutting. Even if there was not any statistical difference between the genotypes, ADF content of Ülkem cultivar was slightly higher than the genotype. In term of NDF content, though there was not any differences amongst the treatments and genotypes in the first cutting, the differences amongst the treatments were significant in the second cutting. NDF ratios ranged from 33.66% to 36.64% in the first cutting. While the lowest NDF content was determined as 24.48% at the genotype with 50 cm row spacing, the highest one was 31.15% at the Ülkem cultivar with 50 cm row spacing in the second cut. The other treatments were in the same statistical group. Fiber (ADF, NDF) accumulation was lower in the second cut, because the plants were harvested earlier growing stage. NDF and ADF ratios of cowpea hay were explained as 32.73 – 33.21% and 30.05 – 30.81% by Ayan et al. (2017).

The CP, ADF and NDF contents of the cowpea genotypes were within the high quality forage group according to standards developed by the Hay Marketing Task Force of American Forage and Grassland Council (Rohweder et al., 1978). As the growing stage increase, crude protein content of forages decreases but ADF and NDF content increase (Kaya, 2008).

Conclusion

In future farming system, the importance of cowpea, known as resistant to high temperature and drought, is likely to increase due to changing climatic conditions. Cowpea can play an important role to fill forage gap by cutting for hay or by grazing during summer-autumn period when pasture yield is very low. In the light of this study, we can say that forage cowpea can be grown as double crop after winter cereals in the coastal area of Turkey like Black Sea Region. Both cv.Ülkem and the genotype can be recommended for forage as double crop with 20 – 35 cm row spacings.

Abstract

Drought is the mainly abiotic stress factor and amount and distribution of the rainfall during grain filling period affect bread wheat yield and quality. The study was carried out in the experimental field of Trakya ARI, Edirne (Turkey), in 2008-2009 and 2009-2010 years and 15 genotypes were planted in RCBD in a split-plot with three replications. The main plots were assigned to five moisture regimes, which included 3 drought stress environments, one non-stress and one non-treatment environment. Grain yield, 1000-kernel weight, test weight, protein content, wet gluten, gluten index, hardness and sedimentation value were investigated. Principal component analysis (PCA) and cluster analysis was used to determining for genotypes environment interaction. Principal component analysis (PCA), indicated that the first (20.63%) and second (41.42%) components justified 62.04% of variations between the criteria. According to GGE biplot results Kate A-1 and Tekirdağ was determined as most stable cultivars for grain yield. Mean values of the genotypes varied between 29.7-43.5 g for TKW, 73.6-83.2 kg/hl for test weight, 11.1-13.3% for protein content, 28.5-37.0% for gluten value, 34.3-56.0% for sedimentation, 68.9-95.3% for gluten index and 383.0- 658.3 for grain yield. When all parameters were evaluated using the PCA analysis, protein ratio, gluten value and hardness were involved in the same group, while yield and gluten index and sedimentation value and test weight were grouped in two different groups. The cluster analysis was done and 15 genotypes divided into 3 clusters based on Ward's method. The cluster I and II were more clearly separated than cluster 3. The cluster analysis revealed that considerable variation existed among genotypes that could be implicated in selection of bread wheat for the development or improvement of cultivars. According to the results of the study, genotypes with appropriate combination in terms of examined traits were selected for national breeding program of bread wheat.

Keywords: *Bread wheat, biplot analysis, genotypes main effect, genotypes environment interaction, quality parameters*

Introduction

Trakya region is located in the North western part of Turkey and mostly winter and facultative bread wheat is cultivated. Due to various environment condition (rainfall and temperature) could cause some production problem related with lower yield and quality in production (Öztürk and Korkut, 2017). Performance trials have to be conducted in multiple environments because of the presence of GE. Variety trials provide essential information for selecting and recommending crop cultivars. However, variety trial data are rarely utilized to their full capacity. Although data may be collected for many traits, analysis may be limited to a single trait (usually yield) and information on other traits is often left unexplored. Furthermore, analysis of genotype by environment data is often limited to genotype evaluation based on genotype main effect (G) while genotype-by-environment interactions (GE) are treated or a confounding factor (Yan and Tinker, 2006). Almost all breeding programs in the world aim to improve varieties with stable yields. The yield stability is generally grouped as static or

dynamic stability (Pfeiffer and Braun, 1989). Therefore, selection of wheat genotypes should be adapted to drought stress. In addition, drought tolerance mechanism should be identified during the development of new cultivars in order to increase the productivity (Rajaram et al. 1996). Stable yield performance of genotypes under both favorable and drought stress conditions is vital for plant breeders to identify drought tolerant genotypes (Pirayvatlou, 2001). Moreover, high-yielding genotypes under optimum conditions may not be drought tolerant (Blum, 1996). Therefore, many studies preferred the selection under stress and non-stress conditions (Rajaram and Ginkel, 2001).

The objective of this study was to evaluate the performance of the advance genotypes and cultivars and to investigate their yield stability across various environment conditions over two years and five environments.

Material and Methods

The research was carried out in the experimental field of Trakya Agriculture Research Institute, Edirne (Turkey) (41 m above sea level, 41º64´ N, 26º59´ E), during two years (2008-2009 and 2009-2010) and 15 genotypes were evaluated in randomized completely blocks design (RCBD) in a split-plot with three replications. Plot size was 6 rows, 6 m long and 17 cm between the rows. The main plots were assigned to five moisture regimes, which included 3 drought stress environments, one non-stress and one non-treatment environment. Grain yield, 1000-kernel weight, test weight, protein content, gluten value and gluten index, hardness and sedimentation were investigated. Cultivars Kate A-1, Gelibolu, Pehlivan, Tekirdağ, Selimiye, Aldane, Bereket, Flamura-85, Golia and 6 advanced lines were investigated. Drought treatments are placed on main parcel and genotypes on the sub-plot. Droughts were created under mobile rain shelter at various plant growth stages from shooting up to maturity. A mobile rain shelter was used to exclude rain and induce drought stress. In this experiment, all parcels were covered only when raining. A drip irrigation set was used and each plot was irrigated separately by controlling dripping irrigation system. The Zadoks Decimal Code (GS) was used to describe plant growth stages. The experiment consisted of five treatment; DS1: Drought stress applied from GS31 (stem starts to elongate) to GS51 (10% of spikes visible), DS2: Drought stress applied from GS51 (10% of spikes visible) to GS94 (over-ripe, straw brittle), DS5: Drought stress applied from GS31 (stem starts to elongate) to GS94 (over-ripe, straw brittle), one main plot was non-treatment and one main plot non-stress treatment. The statistical analyses of measurements were performed by using statistics program for and the differences among the means were compared with L.S.D at a 5% significant level (Gomez and Gomez, 1984; Kalaycı 2005) and PCI analyses.

Results and Discussion

The analysis variance for the yield and quality components was performed and given in Table 1, and 2. In the study 15 genotypes performance trials were tested at two years five locations to investigate yield and quality components based on Principal Component Analysis. The results of variance analyses showed that there were significant differences ($p<0.01$) among genotypes. The highest grain yield with 658.3 kg da^{-1} was determined in cv. Bereket and followed by genotypes BBVD7 with 651.0 kg da^{-1} and Kate A-1 with 631.5 kg da^{-1} (Table 1). The mean yield of the genotypes was 583.0 and biological yield 2252.9 kg da^{-1}, respectively. Mean values of the genotypes varied between 29.7-43.5 g for 1000-kernel weight, 73.6-83.2 kg/hl for test weight, 11.1-13.3% for protein content, 28.5-37.0% for gluten value, 34.3-56.0% for sedimentation value, 68.9-95.3% for gluten index.

A genotype having stabile grain yield across the environment condition is very important in wheat. Genotype x environment interaction is a mainly issue for plant breeders in improving high yield across variable environments. Stability analysis showed that there was a wide variation among genotypes. Cultivar Bereket produced the highest yield in all environments averaged for two years and five environments. Genotypes Pehlivan, Bereket, and BBVD7 produced high biological yield over two years five environment.

An ideal genotype should have both high mean performance and high stability across environments. Therefore, genotypes located closer to the ideal genotype are more desirable than others. Thus, Aldane and Pehlivan were more desirable than G15 and G14 even though Bereket had higher average grain yield. G15 was the poorest genotype because it was consistently the poorest. The angle between two parameters indicates their similarity in response to the environments. An acute angle (test weight and sedimentation, protein and hardness) means that the two parameters responded similarly and that the difference between them was proportional in all environments. An obtuse angle (gluten and gluten index) means that the two parameters responded inversely and wherever the first parameter performed well the other parameter performed poorly. A right angle indicates that the two parameters (TKW and gluten value) responded to the environments independently (Figure 1).

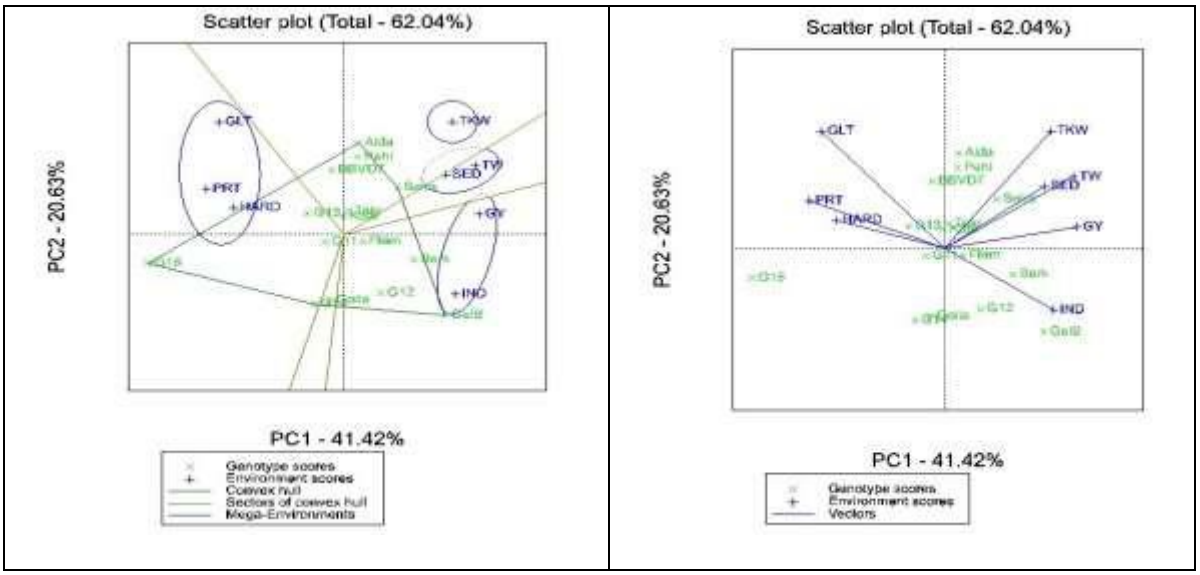

Figure 1. The GGE biplot to show which genotypes performed bets in which environments and a genotype by trait biplot representing 15 winter wheat genotypes measured for eight traits and polygon views of the GGE-biplot on symmetrical scaling for the which-won-where pattern for genotypes and environments

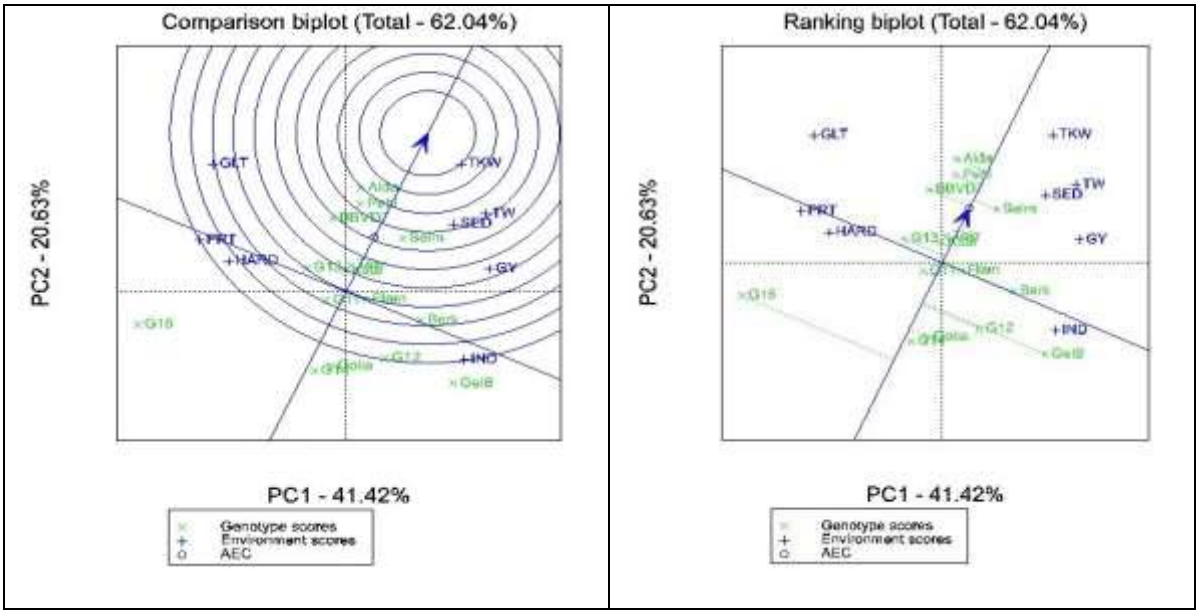

Figure 2. The average-environment coordination view to rank genotypes relative to an ideal genotype (the centre of the concentric circles) and the average-environment coordination view to show the mean performance and stability of the genotypes

Biplot analysis has evolved into an important technique in crop improvement and agricultural research. GGE biplot analysis provides an easy and comprehensive solution to genotype by environment data analysis, which has been a challenge to plant breeders, geneticists, and agronomists. It not only allows effective evaluation of the genotypes but also allows a comprehensive understanding of the target environment and the test environments (Yan and Tinker, 2006).

The distance between two genotypes approximates the Euclidean distance between them, which is a measure of the overall dissimilarity between them. In the study, Aldane and G15 are very different whereas cultivars Aldane and Pehlivan are quite similar. The dissimilarity can be due to difference in mean investigated parameters (G) or in interaction with the environments (GE).

The equality lines divide the biplot into sectors, and the winning genotype for each sector is the one located on the respective vertex. In this study, the five environments fall into two sectors. Aldane was the winner in first group environments, and Gelibolu was the winner for the other environments. This pattern suggests that the target environment may consist of two different mega-environments and that different cultivars should be selected and deployed for each. A genotype by trait biplot can help understand the relationships among traits (breeding objectives) and can help identify traits that are positively or negatively associated, traits that are redundantly measured, and traits that can be used in indirect selection for another trait. It also helps to visualize the trait profiles (strength and weakness) of genotypes, which is important for parent as well as variety selection (Yan and Tinker, 2006; Yan and Kang 2003). The biplot in Figure 1 presents data of 15 genotypes determined for eight traits. Across the 15 tested genotypes, sedimentation with test weight and protein ratio with hardness was positively associated. Protein ratio and hardness was negatively correlated with grain yield. Also, wet gluten value was negatively correlated with gluten index. 1000-kernel weight was independent of gluten value. These relationships suggest that it is possible to combine higher protein ratio and hardness, higher test weight and sedimentation in a single genotype.

The cluster analysis was done and 15 genotypes were divided into 3 clusters based on Ward's method. The cluster I and II were more clearly separated than cluster I. In the first group of cluster 6 genotypes and in second group of cluster 8 genotypes are located. The cluster analysis revealed that considerable variation existed among genotypes that could be implicated in selection of bread wheat for the development or improvement of cultivars.

Conclusions

Because of the various environment conditions yield and quality in wheat varies and GGE biplot analysis provides an easy and comprehensive solution to genotype by environment data analysis and it not only allows effective evaluation of the genotypes but also allows a comprehensive understanding of the target environment and the test environments. Drought is the mainly abiotic stress factor and low moisture during grain filling period affected bread wheat yield and quality. Based on mean value Pehlivan had higher 1000-kernel weight, and Selimiye had higher test weight. According to sedimentation Aldane had higher value and G15 had higher protein ratio and gluten value across two years five environment. Principal component analysis (PCA), indicated that the first and second components justified 62.04% of variations between the criteria. According to GGE biplot results Kate A-1 and Tekirdağ was determined as most stable cultivars for grain yield. Aldane and Pehlivan were more desirable than G15 and G14 even though Bereket had higher average yield. G15 was the poorest genotype. Test weight and sedimentation also protein and hardness responded similarly and that the difference between them was proportional in all environments. Aldane and G15 are very different whereas Aldane and Pehlivan are quite similar. Based on biplot analyses, sedimentation with test weight and protein ratio with hardness was positively associated. Protein ratio with hardness was negatively correlated with grain yield. Also, gluten value was negatively correlated with gluten index. When all parameters were evaluated using the PCA analysis, protein ratio, gluten value and hardness were involved in the same group, while yield and gluten index and sedimentation value and test weight were grouped in two different groups. The cluster analysis was done and 15 genotypes divided into 3 clusters based on Ward's method. The cluster analysis revealed that considerable variation existed among

genotypes that could be implicated in selection of bread wheat for the development or improvement of cultivars. According to the results of the study, genotypes with appropriate combination in terms of examined traits were selected for national breeding program of bread wheat.

Abstract

This research was conducted to assess yield and some yield components of 65 advanced bread wheat mutant lines of M_6 generation selected from M_4 populations of 4 different bread wheat genotypes. They were sown using augmented design consisting of five blocks of which every block had 13 mutant advanced lines and 4 standard varieties (parents) in the 2014-2015 growing season. According to the data obtained from the experiment, there was a great variation for plant height (69.15-119.56 cm), spike length (9.26-11.78 cm), number of grains per spike (30.59-59.84), grain weight per spike (1.43-3.13 g), harvest index (32.57-48.37%), thousand kernel weight (34.13-55.93 g) and grain yield (471.20-951.45 kg/da). The 33 lines for plant height, 22 lines for spike length, 21 lines for number of grains per spike, 31 lines for grain weight per spike, 35 lines for harvest index, 30 lines for 1000 grain weight and 33 lines for grain yield have been found to perform better than standard genotypes. According to the results of study, advanced mutant lines that were superior to the standard types in more than one trait were MT35 (IB-400), MT14 (B-100), MT27 (IB-300), MT19 (IB-200), MT20 (IB-200) and MT15 (IB-100). These mutant lines were selected for yield trials when compared to check cultivars, and they may prove useful for yield improvement in wheat breeding programme. Gamma irradiations with 100 and 200 Gy may be more beneficial for yield improvement in wheat mutation breeding.

Key words: *Bread wheat, mutant line, augmented, grain yield, yield components.*

Introduction

Mutagenesis and hybridization are generally the most commonly used breeding methods to develop new superior varieties. Mutation breeding has some advantages compared to cross breeding. When comparing mutation and hybridization; the occurrence of even a few desirable mutation in high yielding varieties has the great advantage of becoming homozygous and expressing its superiority within a couple of generations after induction in M_2 or M_3 as compared to F_6 or F_7 generations in case of hybridization (Chakraborty and Paul, 2013). Mutation breeding has become an appropriate option to improve plant characters when conventional breeding does not work, or the desired traits were recessive, or improving another character in an established plant variety, or improving one or two main character(s) (Ahloowalia and Maluszynski, 2001 and van Harten, 1998). In addition, mutagenesis is able to isolate mutant with multiple characters, as compared to transgenese where only line can be introduced, it's the major advantage of induce mutations **(**Louali *et al.,* 2015**).** Mutation breeding can be applied to improve a specific character without changing other characters and it is possible to improve a single line without causing an important disturbance in the genome. Furthermore, it may create a new character that was not belong to parental plants The mutants developed in wheat have a great potential for direct release and for inclusion in hybridization breeding programs (Sakin *et al.,* 2005). The released mutant cultivars in different crops had great economic impact on agriculture and food productions and added billion of dollars in the economy of many countries (Jain, 2006). More than 3000 varieties of different crops have been officially released by mutation breeding technique. Mutation induction with radiation has been the most frequently used method to develop direct mutant varieties (64% with

gamma-rays, 22% with X-rays), accounting for about 90% of obtained varieties (Ahloowalia, et al. 2004). Gamma ray mutagen was effective in broadening genetic variability and increasing means of wheat cultivars for grain yield and its components, helping plant breeders to practice an efficient selection in the M_2 and next mutated generations (Khanna *et al* 1986, Al-Naggar *et al* 2007). Mutant populations have now been created for many cereal crops, including rice (Suzuki *et al.*, 2008), durum wheat (Başer *et al.*, 1997, Sakin and Yildirim, 2004) and bread wheat (Slade *et al.*, 2005). The goal of a wheat breeding program is to develop superior genotypes as a result of many years of selection. Early generation selection is based on visual observations of yield components (ear length and size, number of ears, number of spikelets per ear), disease resistance, tillering potential, lodging resistance and seed quality. In the early stage of selection process, there could be insufficient seed of the new treatments' to undertake replicated experiments or the number of genotypes could be very large to manage in terms of resources. Efficient evaluation of such large numbers of lines in field experiments is laborious, expensive, and difficult to manage because of the confounding effects that genotype x environment interaction and soil heterogeneity. Therefore, augmented designs have been developed for the evaluation of genotypes in the early stages of a breeding program (Federer, 1956). Control treatments are used in these designs with replications in check plots, in order to evaluate the genetic material with no replications. More sophisticated augmented designs allow for the adjustment of test varieties by rows and columns (Federer and Raghavarao, 1975; Lin and Poushinsky, 1983). The efficiency of the analysis over another is usually measured in terms of reduced error variance, expected error mean square, or average standard error of the difference between genotype means (Binns, 1987; Cochran and Cox, 1957; Magnussen, 1990). The average standard error of the difference (SED) was reported to be more appropriate since it is used for comparison among genotypes using the same scale as the traits (Binns, 1987, Cullis and Gleeson, 1991; Gleeson, 1997).
In this study, it was aimed to evaluate the yield and yield components of M_6 advanced bread wheat mutant lines selected from M_4 populations induced different gamma rays of 4 different bread wheat genotypes using augmented design.

Material and Methods

Experimental site and growing conditions: This study was conducted out at the University of Tekirdağ Namık Kemal, Faculty of Agriculture, Department of Field Crops, Turkey in the 2014-2015 growing season. Tekirdağ district locates at latitude 40^o 36'-40^o 31' and longitude 26^o 43'-28^o 08'and altitude is 10 m. The total precipitation was 435.1 mm and the average temperature was 11.5 ^oC during the 2014-2015 wheat growing season (November, 2014-June, 2015) when the experiment was conducted. It is noted that the annual precipitation is about 30 mm lower than the long term average (466 mm) and the average temperature is similar to the long term average (11.5 ° C). According to soil analysis results, experimental area's soil was clay-loam, slightly acidic (pH 6.5), limeless, and poor (1.08%) in the organic matter.
Experimental materials, gamma irradiation and design: Four bread wheat (*Triticum aestivum* L.) genotypes, Avusturalya, Bezostaja 1, Kate A-I and IBWSN4 were used as the experimental material. The moisture contents of seeds of wheat genotypes used in the study were 12.1% for Avustralya, 11.4% for Bezostaja 1, 11.7% for Kate A-I and 12.0% for IBWSN4. Gamma treatment was obtained from ^{60}Cobalt, Ob-Servo Sanguis Co-60 Research Irradiator with isotope model, while the dose rate was 2.190 kGy h^{-1} in before the 2009-2010 growing season sowing at the Turkish Atomic Energy Authority, Sarayköy Nuclear Research and Training Center, Ankara, Turkey. Right after irradiation, the experiment was set up using a total of 20 M_0 (100, 200, 300, 400 and 500 Gy) combination seeds together with the un-irradiated (control) in the experimental field of the Field Crops Department of the Faculty of Agriculture of Tekirdağ Namık Kemal University during the growing season of 2009-2010.

The seeds obtained from the harvested plants in M_1 generation were sown in 2011-12 (M_2), 2012-13 (M_3) and 2013-14 (M_4) growing seasons as 20 cm row distance in 5 meters of 6-row plot with 4 replicates and as 400 seeds in each row. The experiment was carried out in augmented design with 5 blocks with 65 advanced bread wheat mutant lines of M_6 generation selected from M_4 populations of 4 different bread wheat genotypes and their parents (Table 1). Each block included 13 advanced bread wheat mutant lines and 4 standard bread wheat genotypes (A, IB, K and B).

Sown were made on Nov.7, 2014 by hand at the rate of 500 seeds per m^2 and were 5 m in length, with 2 rows 0.2 m apart. Nitrogen and P_20_5 at 140 and 70 kg ha^{-1}, respectively, were incorporated into the soil as compound fertilizer (20-20-0) before sowing, urea during tillering and ammonium nitrate before heading. The crop was kept free of weeds by hand hoeing when necessary. Morphological and yield characters were recorded on 15 random and guarded plants to study the effect of irradiation doses on the studied genotypes on plant height (PH-cm), spike length (SL-cm), the number of grain per spike (NGS-no), grain weight per spike (GWS-g), thousand grain weight (TGW-g), harvest index (HI-%), and grain yield (GY) was calculated as kg/da. The variance analysis on obtained data was performed according to the augmented design using the JUMP 5.0 statistical package program, and the differences between the averages were determined by Student's test.

Results and Discussion

As a result of the variance analysis, there were statistically significant differences in the level of 0.01 probability among mutant lines means for plant height, spike length, thousand kernel weight and grain yield; significances of them for number of grains per spike, grain weight per spike and harvest index were statistically significant at the 0.05 probability level. Mean performances of checks and adjusted performances of mutant bread wheat lines for investigated characters are given in Table 2.

Plant height (cm): One of the most obvious significant effects of mutagen treatments on plants is the decreases occurring in the plant height. In our study, the average plant height of 65 advanced bread wheat mutant lines in M6 generations ranged from 69.13-119.56 cm, and the average plant height of standard genotypes ranged from 92.86-117.74 cm (Table 2). The shortest plant height among the standard genotypes was determined for IBWSN-4 line, followed by Kate A1 with 100.52 cm. The longest plant height among standard genotypes was measured in Australian variety (Table 2). 23 mutant lines gave a shorter plant height than the standard genotype IBWSN-4, which has the shortest plant height. Among them, 13 lines were below the plant height value of 90.00 cm, which is recommended for our region to avoid lodging problems.

Table 2. Mean performance of checks and adjusted performance of mutant bread wheat lines.

As a result, it is understood that these 13 advanced bread wheat mutant lines should be evaluated in the next generations in terms of plant height. Our results are supported by findings of Shubhra *et al.* (2013), explaining that mutant lines with shorter plant length can be obtained as a result of gamma irradiation.

Spike length (cm): One of the most important yield components affecting wheat yield is the spike length and it is accepted as one of the most important selection criteria in wheat breeding as well. Previous studies have shown that mutagen applications cause significant changes in spike length in wheat (Mohammad *et al*., 2004, Farag and El-Khawaga, 2013) In the study, the spike length of 65 advanced bread wheat mutant lines ranged from 7.61 to 11.78 cm, and the spike length of standard genotypes ranged from 10.46 to 10.78 cm (Table 2). Among the mutant lines examined in the experiment, 13 lines (MT14, 35, 31, 48, 36, 27, 17, 25, 64, 40, 37, 41 and 42) formed longer ears than all standard genotypes. These results are similar to those of Githinji and Birithia (2015), who also reported highly significant differences for spike length and mutant bread wheat lines produced the longest spike as compared to the parent wheat variety.

Number of grains per spike (no): In the case of wheat improvement, the number of grains per spike is one of the selection criteria considered as the most important main yield component in the wheat breeding studies. It has been determined that 65 advanced bread wheat mutant lines tested in the M_6 genome exhibit a wide variation in the number of seeds per spike from 30.59 to 59.88, while it is as low as 42.98 to 47.76 no (Table 2). Among the tested lines, 21 lines (MT61, 44, 40, 31, 59, 28, 27, 14, 42, 33, 35, 32, 50, 47, 29, 36, 51, 53, 22, 54 and 48) was found to have a higher number of grains per spike than the standard IBWSN-4 genotype, giving the highest mean. These lines showed an increase in number of grains per spike as compared to the parent varieties. These results collaborate with those of Ahmad *et al.* (2011) who found a highly significant difference ($p \leq 0.01$) in genotypes showing diverse types of wheat. Rachovska and Dimova (2000) stated that while, the number of grains were the most sensitive traits to mutagenic action, and were suggested as criteria for investigating the action of gamma rays.

Grain weight per spike (g): One of the most important yielding factors affecting wheat yield is the grain weight per spike and it is accepted as one of the most important selection criteria in wheat breeding as well. In terms of this character, means of the grain weight per spike for the 65 advanced bread wheat mutant lines in the M_6 generation ranged from 1.43 to 3.13 g, while the standard genotypes ranged from 1.95 to 2.30 g indicate variation was wider in lines than that of standard genotypes (Table 2). Among them, 19 mutant lines (MT14, 31, 28, 33, 30, 27, 32, 35, 37, 29, 36, 42, 44, 6, 7, 53, 19, 11 and 22) were a higher grain weight per spike than the IBWSN-4 standard genotype, which gave highest averages. These results suggest that these 31 mutant lines should be considered as priority in terms of grain weight per spike and agree with results of Sobieh and Ragab (2000) who have reported that increased doses of mutations have resulted in increases for grain weight per spike.

Harvest index (%): The harvest index, which is the ratio of economic yield to biological yield, is an important selection criterion. It is desirable that the harvest index be as high as possible (even closer to 50%) in wheat breeding. The harvest index values of sixty-five advanced bread wheat mutant lines ranged between 32.57% and 48.37%, and between 35.39% and 40.60% in standard genotypes. 35 mutant lines (MT33, 37, 30, 47, 11, 29, 42, 50, 44, 48, 46, 27, 32, 28, 21, 35, 31, 51, 4, 19, 17, 20, 7, 6, 14, 52, 39, 15, 10, 62, 58, 36, 22, 43 and 9) were the highest harvest index value compared to standard varieties. Fourteen mutant lines (MT33, 37, 30, 47, 11, 29, 42, 50, 44, 48, 46, 27, 32 and 28) performed well with harvest index averages of over 45%. The findings of Rahimi *et al.* (2011), which explains that lines with higher harvest index averages than the rootstocks can be developed with gamma irradiation, proves our results.

Thousand grain weight (g): Thousand grain weight (g) or seed index which is indicator of grain size and flour yield in wheat is important main yield contributing trait. In our study, the thousand grain weight means of the 65 advanced bread wheat mutant lines ranged from 34.13 to 55.93 g, while the standard genotypes' means ranged from 36.9 to 47.04 g. Among the advanced bread wheat mutant lines, 30 lines (MT43, 41, 5, 49, 21, 46, 65, 39, 8, 7, 20, 29, 52, 40, 19, 31, 28, 30, 36, 38, 6, 23, 24, 18, 9, 37, 12, 35, 25 and 53) were a higher 1000-grain weight than the standard genotype. Fifteen mutant lines (MT43, 41, 5, 49, 21, 46, 65, 39, 8, 7, 20, 29, 52, 40 and 19) draw attention with a averages of thousand grain weight above 50 g (Table 2). Our results show that a wide variation can be achieved with the application of mutagen in terms of 1000 grain weights similar to results of Singh and Balyan (2009) who illustrated mutant lines with larger grains than the parents can be obtained as a result of gamma irradiation.

Grain yield (kg da^{-1}): The main purpose of plant improvement is to increase grain yield obtained from unit area. Grain yield being polygenic and is highly influenced by cultivar, environment and cultivar x environment interactions. Taking into consideration the other features examined, it is seen that mutagen application causes a lower variation in grain yield. The average performance of grain yield (kgda^{-1}) of all genotypes is depicted in (Table 2). In the study, grain yield of advanced bread wheat mutant lines ranged from 471.20-941.45 kg da^{-1}, while grain yield of standard genotypes ranged from 607.40-855.60 kg da^{-1} (Table 2). Results regarding to the trait revealed that the higher grain yield was observed in 10 mutant lines (MT53, 19, 33, 35, 14, 20, 42, 40, 27 and 15) as compared to the other genotypes, our results are in confirmation with those of Ayub *et al.* (1989) who stated that the effect of different dose of gamma rays irradiation on grain yield of wheat varieties responded differently in different varieties. As a result, it can be said that it would be appropriate to take these 10 mutant lines into the pre-registration yield trials in terms of grain yield.

Conclusion

The mutant MT53, MT19, MT33, MT35, MT14, MT20, MT42, MT40, MT27 and MT15 out yielded among all lines and stood first as compared to other mutants and check varieties in yield associated traits studied. Among them, MT35, MT14 and MT27 over performed for all yield components except thousand grain weight. As a result, MT35, MT14, MT27, MT19, MT20 and MT15 should be included in further breeding programs for exploitation of its genetic potential in new cross combinations. When the pedigrees of these promising mutant lines were examined (Table 1), the majority of the mutants originated from populations irradiated with gamma rays of 100 and 200 Gy suggesting that these gamma doses may be more beneficial for yield improvement in wheat mutation breeding.

Abstract

This study carried out in Çukurova University of Turkey was started with six runner strawberry varieties and genotypes: 'Sevgi', 'Rubygem' 'Kaşka' cultivars and '291', '60' and '36' hybrid genotypes. These materials were waited in 15% sodium hypochlorite solution for 10 minutes in order to surface sterilization and then were rinsed with sterile water in tissue culture laboratory. After sterilization, shoot tips of plants were extracted by sterile forceps and scalpels under a stereobinocular microscope in laminar flow and placed on hormone free Murashige and Skoog (MS) nutrient medium for initiation development during four weeks. Then, the explants were transferred to the MS medium containing 1 mg L^{-1} 6-Benzylaminopurine (BAP) for shoot proliferation. After four weeks, the effects of genotypes on root number, root length and explant weight were investigated. The number of root varied from 4.11 ('Sevgi') to 2.33 ('36'). Root length was changed between 1.61 ('36') and 0.64 cm ('Sevgi'). Our results showed that root length and number were negatively correlated with each other due to nutrition competition. At the same time, there was the difference in rooting capacity even in the same genotype. Therefore, at the end of study, the explants were divided to tree classes (well rooted, medium rooted and non-rooted) to determine the effect of root on the percentage of survival *in vitro* plants during acclimatization stage. The genotype, amount of root and their interaction were significantly effective on the acclimatized plants successfully. As expected, the percentage of survival plants was influenced from the number of roots. The highest percentage for rooting obtained was 75.8%. Also, *in vitro* plants obtained from 'Rubygem' variety did not need many roots to survive. However, any *in vitro* plants could not live under non rooted condition in this cultivar. This study presents preliminary results of a project aimed testing different types of plant growth regulators and their different doses on important breeding varieties and genotypes using shoot tip culture. These pre-results will be useful for us in terms of knowing the tissue culture capacities of our genotypes and varieties.

Key words: Strawberry, *in vitro*, Shoot tip, Rooting

Introduction

Strawberry (*Fragaria x ananassa*) is one of the most preferred fruits due to their rich vitamin content and their unique flavor. According to Turkish Statistical Institute (TUİK) data, in the Mediterranean region of Turkey, strawberry cultivation covers 61 023 hectares area in 2016 (TUİK, 2017), demanding 335-366 million seedlings annualy in this region. The choice of proper and high quality variety, is the first step of successful production in agriculture. . Seedling diameter is a very important quality parameter in strawberry cultivation and therefore, A+ seedlings having ≥15 mm diameter should be considered (Paydaş Kargı and Sarıdaş, 2012). In addition, selection of varieties resistant to soil-borne diseases and growing these varieties in disease-free areas are important for efficient production. In recent years, meristem culture studies have been carried out in order to produce high number of disease and virus free plantletsRunners are normally used for mass propagation of strawberry. Soil-borne disease in areas where material for seedling production are used can spread easily with

planting materials when vegetative methods are used and causes loss of yield. Meristem culture is known as one of tissue culture methods used efficiently in obtaining disease and viruses free seedlings. Meristem culture also ensures that the important genetic materials obtained are preserved. Success of tissue culture is determined by genotype, explant type, season, nutrient medium, plant growth regulators.

In this study, the effect of the amount of roots *in vitro* propagated plantlets on viability of plants at the acclimatization step was investigated. Number of roots, root length and explant weight were considered comparatively among tested genotypes and cultivars. In addition to, survival percentage of plants was also determined.

Materials and methods

Three strawberry variety candidates obtained by crossing, namely: '291' (Rubygem x Kaşka), '60' (Fortuna x Sevgi) and '36' (Fortuna x Sevgi) and their parents (except Fortuna) were used. These three candidates were selected by considering of aroma and firm-flesh features among F1 hybrid individuals. Surface sterilization was performed by washing materials in 15% sodium hypochlorite solution including 1-2 drops Tween-20 for 10 minutes followed by rinsing with sterile water 4-5 times. Following sterilization, shoot tips were extracted using sterile forceps and scalpels under a stereobinocular microscope in laminar flow and cultured in glass tubes containing growth regulator free Murashige and Skoog (MS) (Murashige and Skoog, 1962) medium for initiation development. The cultures were incubated at the 25±2°C under 3000 lx in 16 h photoperiod. After establishment they were transferred in to MS medium supplemented with 1.0 mg L^{-1} BAP After four weeks, root number, root length (cm) and explant weight (g) were investigated in each genotype and cultivar.

The experiment was conducted as two factors randomized complete block design as split plot with three replications. The obtained data were analyzed with the statistical program JMP version 5.0.1 (SAS Institute Inc., Cary, NC). ANOVA was carried out to determine the effects of the different genotype and rooting conditions (non rooting, medium rooting and well rooting) on root number, root length, explant weight and survival percentage. A least significant difference (LSD) test was carried out to examine the differences among groups. Comparisons that yielded $P \leq 0.05$ were considered to be statistically significant.

Results and discussion

Data obtained from this study are summerized in Table 1-4. In this study, the *in vitro* plants were evaluated in three groups; non rooted, medium rooted and well rooted for each genotype and variety. And the genotypes and varieties were compared among each other.

There was a significant differences between root lengths of different rooting levels and genotypes-varieties. The differences between interactions of these two factors were not significant. In this respect, the highest values were obtained from the genotypes '36' (1.61 cm), '60' (1.57 cm) and '36' (1.51 cm) from the same statistical group. The root length of the 'Sevgi' variety revealed the lowest value with 0.64 cm. The root lengths of medium and well-rooted plants were found to be close to each other and the difference of 0.30 cm between them was statistically insignificant (Table 1).

Table 1. Root length of different genotypes under various root properties (cm)

Rooting	Genotype						Mean
	291	**Rubygem**	**Kaşka**	**36**	**60**	**Sevgi**	
Non rooting	0	0	0	0	0	0	**0 B**
Medium rooting	1.90	1.50	1.75	2.00	1.70	1.10	**1.66 A**
Well rooting	2.63	1.43	1.02	2.83	3.00	0.83	**1.96 A**
Mean of genotypes	1.51 ABC	0.98 BCD	0.92 CD	1.61 A	1.57 AB	0.64 D	
LSD_{gen}*= 0.62			**LSD_{r}***= 0.44**		**LSD_{genxr}= N. S.**		

(1): Differences between the means were showed with different letters
(2): N.S.: Not Significant, ***: p<0.001; **: p<0.01; * : p<0.05

Root number of genotypes and varieties were determined between 4.11 ('Sevgi') and 2.33 ('36'). The effects of rooting levels on root numbers were found statistically significant. As expected, the root numbers of well-rooted plants were determined to be 6.39 (Table 2).

Table 2. Root number of different genotypes under various root properties

Rooting	Genotype						Mean
	291	**Rubygem**	**Kaşka**	**36**	**60**	**Sevgi**	
Non rooting	0	0	0	0	0	0	0 C
Medium rooting	1.00	2.33	2.67	2.00	2.00	4.00	2.33 B
Well rooting	7.67	7.00	5.00	5.00	5.33	8.33	6.39 A
Mean of genotypes	2.89	3.11	2.56	2.33	2.44	4.11	
LSD_{gen}= N. S			**LSD_{r}***= 1.26**		**LSD_{genxr}= N. S..**		

(1): Differences between the means were showed with different letters
(2): N.S.: Not Significant, ***: p<0.001; **: p<0.01; * : p<0.05

Varieties and genotypes, rooting levels and differences between interactions of these two factors were found statistically insignificant on the explant weight. The heaviest explants were observed as 1.67 g in the 'Kaşka' variety, as 1.44 g in the well-rooted plants and as 2.15 g in the well-rooted plants of the 'Rubygem' variety (Table 3).

Table 3. Explant weight of different genotypes under various root properties (g)

Rooting	Genotype						Mean
	291	**Rubygem**	**Kaşka**	**36**	**60**	**Sevgi**	
Non rooting	1.15	0.97	1.76	1.41	1.39	1.41	**1.35**

(1): Differences between the means were showed with different letters
(2): N.S.: Not Significant, ***: p<0.001; **: p<0.01; * : p<0.05

The factors investigated and their interactions showed statistically significant effect on the viability levels of the plants. The highest viable plants were obtained from the best rooted plants at 75.8%, and non-rooted plants gave the lowest value at 7.08%. 'Rubygem' variety and the genotype '36' having 66.7% survival plants were important in terms of the highest viability rate, they were followed by the genotype '60' (55.0%) and 'Kaşka' variety (47.5%). 'Rubygem' variety and the genotype '36' having medium and well-rooted plants and 'Kaşka' variety having well rooted plants were remarkable with 100% viability (Table 4).

Table 4. Survival rate of different genotypes under various root properties (%)

(3): Angle transform data were bracketed

From the parameters tested it was observed that there is an effect of the rooting levels and the genotypes-varieties on root length and survival rates and the effect of the rooting levels on the number of roots. In addition to, no effect was observed on explants weight of parameters selected. It is also interesting that the surviving plants are also affected by the interaction of two selected parameters. Thus, it has been demonstrated that non-rooted (the genotype '60' and 'Kaşka' variety) and medium-rooted (except genotype '291') plants of some varieties and genotypes can survive.

Many studies have been carried out on strawberry meristem and shoot tips culture until today. These studies are based on different plant growth regulators and their varying doses. In a study carried out by Fatemeh et al. (2010), effect of the plant growth regulators at different concentrations on the rate of micropropagation, rooting and survival *in vitro* plants of the 'Camarosa' strawberry variety was examined using shoot tip technique. As a result, while 2.0 µM Thidiazuron (TDZ) and 4.0 µM BAP combination was found better than others, the highest number of roots, the number of rooted plants and the longest roots were determined in 1.0 µM Naphthaleneacetic acid (NAA), 2.0 µM Indole-3-butyric acid (IBA) and growth regulator-free MS medium, respectively. Yonghua et al. (2005) reported that when IBA concentration was increased to 0.4 mg L^{-1} from 0.2 mg L^{-1} and 1.5 mg L^{-1} TDZ was added to nutrient medium, the percentage of shoot regeneration and the number of shoots per plant increased significantly. Ko et al. (2009) recorded that 1.0 mg L^{-1} BA and 0.1 mg L^{-1} NAA added to MS nutrient medium was better than 0.5 mg L^{-1} BA and 0.02 mg L^{-1} NAA in terms of micropropagation and the multiplication capacity of plant materials was increased by this medium. Adak et al. (2009) examined the effects of different types of hormones and their combinations on the propagation of Camarosa strawberry variety by tissue culture. According to the results obtained from the study, it was reported that TDZ and its application together with IAA significantly affected micropropagation. In addition to, 1.5 mg L^{-1} TDZ and 1 mg L^{-1} Indole-3-acetic acid (IAA) was determined to be the best combination for micropropagation and average 28.46 shoots were obtained using this combination. It was also found that

increased IBA concentration reduced rooting and the highest root growth rate was obtained from medium containing activated charcoal. In a study carried out by Lee et al. (2010), different nutrient mediums (MS, Gamborg B5 and White), their different strength (1/3, 1/2, 1, 2 and 3) and different sucrose doses (1%, 3%, 5% and 8%) were tested in the microprogation success of 'Goha' strawberry variety. Among all of them, 1/2 MS and 1% sucrose were found to be better than the other ones. Increased sucrose content negatively affected shoot length. Adak (2011) recorded reaction of strawberry varieties to different Gibberellic acid (GA_3) doses during the meristem culture process. In terms of micropropagation, 0.4, 0.8, 1.0 mg L^{-1} GA_3, 0.1 mg L^{-1} GA_3 and 0.4 mg L^{-1} GA_3 doses gave the best results for Camarosa, Chandler and Oso Grande varieties, respectively. In the same study, media containing BAP more than 1.0 mg L^{-1} significantly reduced the number of micro shoots in strawberry varieties tested. The best hormone combination was found to be 1.0 mg L^{-1} BAP , 1.5 mg L^{-1} TDZ, 1.0 mg L^{-1} IAA for micropropagation of strawberry by Adak (2016). For rooting, using activated charcoal (AC) instead of auxin was recommended in the same study. For all varieties used in the research, the highest number and the longest roots were obtained from media with 5 g L^{-1} AC. It was found that IBA + AC combination and NAA + AC combination responded similarly and while higher NAA concentration increased callus formation, it decreased rooting capacity.

As seen in these studies, different dosses BAP, IAA, IBA, TDZ, NAA and GA_3 and their combination have been tested in the meristem and shoot tip culture studies of strawberry. Root parameters such as root length, root number, the number of rooted plants, shoot parameters such as shoot regeneration and the number of shoots per plant and the percentage of survival *in vitro* plants were considered.

Conclusion

The breeding studies were supported by biotechnological methods such as tissue culture to the process will accelerate these studies. As our results showed that root length and number were negatively correlated with each other due to nutrition competition. At the same time, there was the difference in rooting capacity even in the same genotype. Therefore, at the end of study, the explants were divided to tree classes (well rooted, medium rooted and non-rooted) to determine the effect of root on the percentage of survival in vitro plants during acclimatization stage. The genotype, amount of root and their interaction were significantly effective on the acclimatized plants successfully. As expected, the percentage of survival plants was influenced from the number of roots. The highest percentage for rooting obtained was 75.8%. Also, in vitro plants obtained from 'Rubygem' variety did not need many roots to survive. However, any in vitro plants could not live under non rooted condition in this cultivar. Shoot tip culture performances of some important breeding genotypes and varieties have been presented with this study. In future studies, it is aimed to obtain more useful information by using with different plant growth regulator combinations and doses.

Abstract

In order to healthy ruminant feeding, high quality forage must be eaten and at least half of feed should consist of forage. Though oat is commonly used as food and feed in the world. In Turkey oats are mainly used for feeding as forage and kernel. Its kernel has high Content of carbohydrate, protein, oil, minerals and vitamins. Protein level of oat kernel can be reached up to 16% and its biological value is similar to the other cereals. Oat kernel has one of the highest oil content among cool season cereals with 6.5%. These properties increased oat kernel nutritive value, palatability and voluntary intake of oat by ruminants. The climatic characteristics of Samsun are very suitable for oat requirements. The aim of this study was to determine the effects of 5 different nitrogen doses, on grain yield and yield components of 2 oat varieties and 1 oat line. The experiment was established according to split plots design with 3 replicates on 11 November 2016. In the study, grain yield, 1000 seed weight, height of plant, number of panicle per square meter and harvest index of oat genotypes were determined. Average grain yields were 2.53, 2.86, 3.37, 3.62 and 3.93 t ha^{-1}, respectively, depending on N doses (0, 50, 100, 150 and 200 kg ha^{-1}). Panicle numbers were also increased with N fertilization, the highest value was obtained from 200 kg ha^{-1} N rate with 467 panicle number m^{-2}. As the N doses increased, grain yield was also increased even though 1000 seed weight decreased.

Keywords: *Oat, Nitrogen dose, Cultivar, Grain yield, Yield components*

Introduction

Oat (*Avena sativa L.*) is an important cereal crop and is commonly grown for food and feed. As compared to the other cereals, oat is considered to be more suitable for growing under marginal lands, including cool-wet regions and unfertile-arid lands (Buerstmayr et al., 2007, Mut et al., 2011). Though oat commonly was used as food and feed in the world, main usage area of oat is feeding as forage and kernel in Turkey. In order to healthy ruminant feeding, they must eat high quality forage and at least half of feed should consist of forage. Its kernel has high content of carbohydrate, protein, oil, minerals and vitamins. Protein level of oat kernel can be reached up to 16% and its biological value is similar to the other cereals. Oat kernel has one of the highest oil content among cool season cereals with 6.5%. These properties increased oat kernel nutritive value, palatability and voluntary intake of oat by ruminants. The climatic characteristics of Samsun are very suitable for oat requirements. The proof of this fact, there is a huge variation of local oat population or ecotypes in Samsun (Kün, 1983). Oat would be very important crop in this region because of its really good adaptation, higher yield, nutritious and palatable for ruminants (Aydin et al., 2010). Oat can be grown as a catch crop from October to July for grain production. Yield potential and response of nitrogen fertilizer of oat is higher than the other cool season cereals (Hartman, 2000; Frazer and Mc Cartney., 2004). Higher N use efficiency can qualify the recommendations and provide technologies that are more adjusted, economically viable and of lower environmental impact, which are decisive conditions in the search for a more

sustainable agriculture (Parry et al., 2011; Prando et al., 2013). Nitrogen fertilization is still very complex and it is worth to research closely. Its effect is very different due to environmental factors (soil conditions, and climate especially rainfall) and genotype. The aim of this study is to determine the effects of 5 different doses of nitrogen, on grain yield and yield components of 2 oat varieties and 1 oat cultivarline.

Materials and methods

This study was conducted to determine the effects of 5 N doses (0, 50, 100, 150 and 200 kg ha^{-1}) on hay yield and mineral contents of 2 oat cultivars (Kahraman and Faikbey) and 1 oat line in Agricultural Research Center of Ondokuz Mayis University. Monthly temperature and rainfall data from November 2016 to May 2017 of the experiment site were 12.5, 5.9, 6.2, 7.5, 9.4, 10.2, 15.3 ^{o}C and 42.4, 81.5, 68.8, 40.1, 65.1, 85.8, 70.9 mm, respectively. The soil of the experiment site was poor in terms of organic matter (1.36 %) and phosphorus (mg/100 g of soil) and medium for potassium (mg/100 g of soil). In experiment, oat planted with 20 cm row spacing and each plot was consist of 6 rows. Consider soil sample analysis, 80 kg ha^{-1} P_2O_5 was applied the whole experiment area. Half of the N doses were applied with seed cultivation, the other part was given when the plants started active growing in spring which BBCH growth stage. There was no irrigation. The experiment was established according to split plots design with 3 replicates in 11 November 2016. Plots were harvested when the oat seeds matured. Plots were harvested at The following traits were performed: grain yield per hectare at 13% moisture; yield components, height of plant, number of panicle per square meter, mass of one thousand grains and harvest index. Resultant data were subjected to statistical analyses according to split plot design in SPSS 17.0. Differences in means were tested with Duncan's multiple range test.

Results and discussion

Significant differences were determined amongst the genotypes and N doses in the point of grain yields. While the highest grain yield was obtained from Faikbey cultivar (3630 kg ha^{-1}) as an average of N doses, Line 38 genotype took place in the same statistical group. Regard the mean of genotypes, the highest grain yields was determined to N200, N150 and N100 doses (3930, 3620 and 3370 kg ha^{-1}, respectively). The lowest grain yield was 2530 kg ha^{-1}, obtained from N0 dose (Table 1). Previous works were also reported similar results indicating that grain yield values increased due to increased nitrogen rates (Rocquigny et al., 2004; Muurinen et al., 2007). The responses of genotypes to N doses were different. While grain yields of Faikbey cultivar and Line 38 linearly increased parallel to N dose increase, grain yield of the Kahraman cultivar increased until N10 dose and then decreased and then increased again (Table 1 and Figure 1).

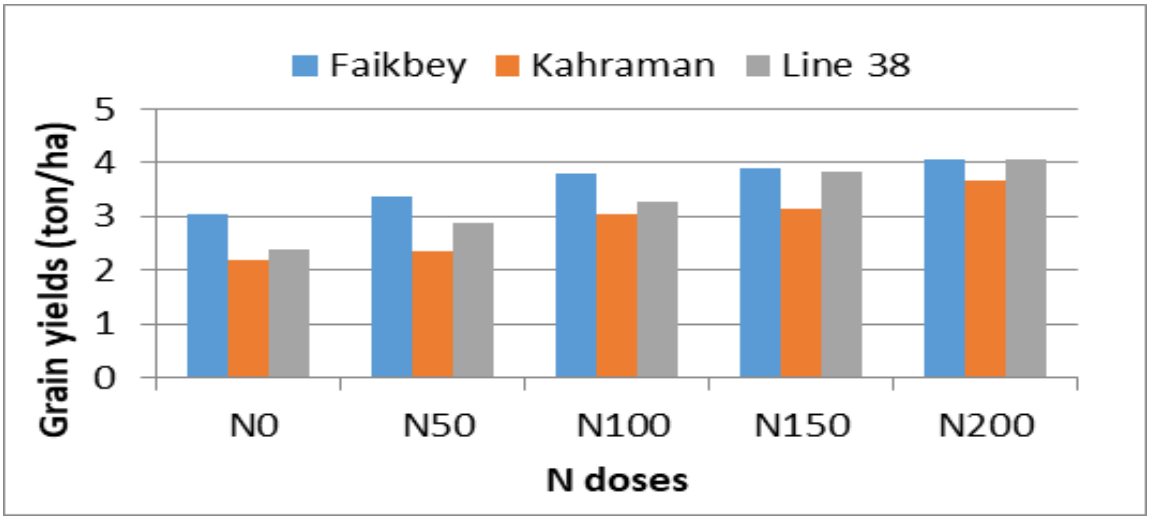

Figure 1. Grain yields of oat genotypes according to N doses

In terms of panicle number there were no differences amongst the genotypes, but differences amongst the N doses were significant. Panicle number m^{-2} were also increased with N fertilization, the highest value was obtained from 200 kg ha^{-1} N rate with 467 panicle number m^{-2} and N150 and N100 doses were in the same statistical group (Table 1). Similar results were also reported in previous works, indicating increased panicle number m^{-2} values with N fertilization (Peltonen-Sainio, 1997; Browne et al., 2006; Maral et al., 2013). Plant height of cultivars/line varied between 130.11 cm and 110.13 cm (Table 1). The average plant height was 111.79 cm for the control plots. It was increased to 115.70, 119.90, 125.80 and 127.50 cm at 50, 100, 150 and 200 kg ha^{-1} N rates, respectively (Table 1). Previous researchers reported that plant height is increased by increasing N fertilization, which supports our results (Chalmers et al., 1998; Shah et al., 2002; Rocquigny et al., 2004; Mohr et al., 2007; Maral et al., 2013). 1000-grain weight (1000-GW) of cultivars varied between 37.36 and 48.80 g. Line 38 had the lowest 1000-GW with 37.36 g (Table 1). Previous oat researchers also reported significant differences among cultivars in terms of 1000-GW (Gul et al., 1999; Shah et al, 2002; Inan et al., 2005). N doses caused to decrease of 1000-GW. It was determined as 43.7 g for control plots. It was decreased to 43.68, 42.29, 41.92 and 41.43 g in 50,100, 150 and 200 kg ha^{-1} N doses. As N doses increases, panicle number m^{-2}, kernel number and yields were also increased, in consequence 1000-GW was decreased.

In terms of harvest indexes there were no differences amongst the genotypes and N doses. The harvest indexes were 15.5%, 15.58% and 16.16% for Faikbey, Kahraman and Line 38, respectively (Table 1). The results were consistent with the findings of Shah et al., (2002); Inan et al., (2005) and Maral et al., (2013). Even though there was not any differences, harvest indexes were slightly increased in n150 and N200 doses.

Table 1. The values about grain yield and some agricultural characteristics obtained from some oat genotypes that was applied different N doses

Cultıvar-line / N Doses	**Plant height (cm)**					
	N0	**N5**	**N10**	**N15**	**N20**	**Average**
Faikbey	118.33	127.93	130.8	135.2	138.27	130.11a

Average	15.12	15.63	15.94	16.69	17.04	

*There is no difference amongst the number indicated same letter in the same column

Conclusion

In the study faikbey cultivar were appeared dominant in all parameters except panicle number were kahraman cultivar become superior. Doses of Nitrogen fertilizer were showed great effect at all cultivars on grain yield, plant height and panicle number m^{-2} N15 and/or N20 doses can be recommended in similar ecological conditions regarding the genotype. But, to clear the recommendation this type study should carry out at least 2 year.

Abstract

Calcareous soil causes iron (Fe) deficiency in many cultivated plants. Strawberries are among those most affected by lime stress among plants. In high-lime soils, sensitive plants such as strawberries, give less yield by not taking certain nutrients, especially iron. In the recent study, some morphological and fruit characteristics of four (Amiga, Festival, San Andreas and YFL) strawberry cultivars were examined in 5 lime doses (0%, 5%, 7.5%, 10%, and 12.5%). The plants were grown in a mix of peat and perlite (2: 1) containing lime at rates reported in 9-liter pots. After planting, fruits were harvested for four months. After this time the plants were removed and the root and stem characteristics were examined. According to the data obtained from a recent study, although there were differences between the varieties of strawberries, little amount of lime was needed for fruitful and high-quality fruit production. However, in high doses, lime led to reduced strawberry yield and quality, and even plant mortality. While 5% lime dose had a positive effect on root collar diameter (33.40 mm 'Amiga', 32.78 mm 'YFL2), crown per plant (7.42 per plant 'Amiga', 6.00 per plant 'YFL') and number of leaves (41.17 per plant 'YFL', 38.50 per plant 'Amiga'), 7.5% lime had a positive effect on root volume (54.67 ml 'Amiga', 41.33 ml 'YFL'), fruit yield per plant (96.99 g 'Amiga', 82.31 g 'Festival'), fruit size (35.68 mm 'San Andreas', 33.20 g 'Amiga') and fruit width (27.71 mm 'San Andreas', 26.21 mm 'Festival'). However, the number of chlorophyll decreased with increase in lime doses. As a result, more specific work is needed to determine the types of strawberries that can be grown in calcareous soils.

Keywords: *Lime, strawberry, high pH and chlorophyll.*

Introduction

Alkaline soils (pH > 7) are the dominant soil type in arid and semi-arid climates. These soils cover more than 30% of the earth's surface (Chen and Barak, 1982). The pH value of these soils varies between 7.5-8.5 depending on calcium carbonate content (Marchner, 2002).

Iron deficiency chlorosis (FeDC) was recorded as the first known nutrient deficiency (Vose, 1982). The FeDC is a common condition in calcareous soils in many crops such as strawberries (*Fragaria x ananassa*). Lime-induced chlorosis is the most common nutritional disorder of plants growing in soil which includes more than 20% $CaCO_3$ (Schinas and Rowell, 1977). As a result of this, significant loss of yields is experienced (Wallace and Lunt, 1960; Zaiter et al., 1991). Although strawberries yield loss, grown in high-lime soils cannot yet be clearly determined, this rate can reach up to 20% in soybeans (Froehlich and Fehr, 1981; Kinkaid, 1986).

Although the iron content in mineral soils is about 2%, and most plants can remove only 1-2 kg/ha of iron from the soil annually. The main underlying cause of iron chlorosis in soils containing high lime is not the poor iron content in the soil. The main reason is that the iron in the soil is converted to relatively insoluble complex molecules, such as $Fe(OH)_2^+$, $Fe(OH)_3$, and $Fe(OH)_4^-$, by the calcium causing the high pH values (Marchner, 2002). In addition, zinc (Melton et al., 1973; Moraghan and Mascagni, 1991), manganese (Jauregui and Reisenauer,

1982), boron (Kluge and Beer, 1979; Keren et al., 1981), and phosphorus (Welp et al., 1983) bonds similarly as relatively insoluble complex molecules in soils containing high lime.
The roots of the plants grown in calcareous soil are adversely affected by the lime-induced chlorosis seen on the leaves and weaker growth (Bertoni, 1995; Perret and Koblet, 1981; Perret and Koblet, 1984). However, since the iron is taken up by capillary roots, the anomalies that may occur in roots may cause the chlorosis (Bavaresco et al., 1991; Perret and Koblet, 1997; Colugnati et al., 1998). Iron uptake and reduction were closely related to the root diameter in *Vitis vinifera* (Bavaresco et al., 1991), and the shoots of the grapevine grown in calcareous soil are shorter than those grown in relatively non-calcareous soils (Bavaresco et al., 1993).
While the high lime content in the soil may be harmful to plants (at different rates depending on species and cultivars), the lack of lime also damages the plants by causing the washing of the nutrients and causing acidity. The Ca^{+2} ion, which stored by binding plant nutrients such as nitrogen (N) and potassium (K), is present in calcareous soils. In addition, the absence of this ion causes the formation of strongly bonded compounds between phosphorus (P)-iron (Fe) and phosphorus (P)-aluminium (Al) (İnal, 1991).
Lime contributes to the relaxation of compact soils (Aydeniz, 1985). In addition, lime promotes the growth of microorganisms and roots by contributing to the aeration of the soil and the water cycle (İnal, 1991). The root length, plant height, and dry matter are positively affected in tomato up to a certain level with the increase of the lime ratio (20%), and the effect becomes negative if the dose increase continues (Aydeniz and Brohi, 1990). In addition, Schaumberger (1990) reported that the increase in pH up to a certain level in corn cultivars 'Mutin' and 'Anjou' affects iron content positively in the roots and leaves. Similarly, Cutcliffe and Blatt (1984) reported that the addition of lime to low pH (4.9) soils up to a certain level, increased the yield and the mean fruit weight in the strawberry cultivar 'Redcoat'.
In this study, the effects of different lime doses on some plant and fruit characteristics of 4 strawberry cultivars were investigated.

Material and Method

This study was carried out in the Greenhouse of Department of Horticulture, Faculty of Agriculture at Selçuk University in 2016. In this study, effects of 5 lime doses (0%, 5%, 7.5%, 10% and 12.5%) on some plant (root collar diameter, root volume, crown number per plant, leaf number per plant) and fruit characteristics (fruit yield per plant, fruit length, fruit width and mean fruit weight) of 4 strawberries (*Fragaria x ananassa*) cultivars (*cv*.) (Amiga, Festival, San Andreas and YFL) were investigated.
Seedlings was planted in 9-liter pots containing 3:1 peat, perlite, and lime (0%, 5%, 7.5%, 10% and 12.5%) in March. The study was set up with 3 replications and 5 plants per replicate, according to randomized complete blocks design. Fertilization, irrigation, pest and weed control has been regularly treated according to strawberry producing protocols.
Root collar diameter (with Absolute Digimatic model CD-15CPX produced by Mitutoyo Corporation in Japan), root volume (immerse into water), crown number per plant (number of branch crown) and leaf number per plant were investigated in 5 plants in each replication at the middle of November 2016. At the same time, fruit yield per plant, fruit width (fruit diameter), fruit length (with Absolute Digimatic model CD-15CPX produced by Mitutoyo Corporation in Japan), fruit width (fruit diameter) and mean fruit weight (with CAS MW-II 600 precision scale) were investigated from July to October 2016. Because the cultivars used in the experiment were short day cultivars, they were covered with black plastic in order to get fruit in July and August.

The experimental data were collected and subjected to analysis of variance (ANOVA) using SPSS 20.0 software (IBM Corp. Released 2011, IBM SPSS Statistics for Windows, Version 20.0. Armonk, NY: IBM Corp.). The means were separated by multiple Duncan's test at $p \leq 0.05$.

Results and Discussions

1.Morphological Characteristics

The crown diameter (CD) was measured in November 2016 by digital caliper when plants were removed. As can be seen in Table 1, the differences between the results obtained from the study (both between treatments and cultivars) were statistically significant ($p \leq 0.05$). The highest CD values of 4 strawberry cultivars (Amiga: 33.40 mm, Festival: 31.26 mm, San Andreas: 23.96 mm, and YFL: 32.78 mm) were obtained from 5% lime treated plants. Second highest values were 0% treatment in Amiga (30.45 mm), Festival (23.91 mm), and San Andreas (21.49 mm), while 7.5% lime treatment in YFL (28.99 mm). The lowest values were obtained on 12.5% lime treatment as expected (at 10% in San Andreas "15.14 mm" and YFL "22.64 mm") in Amiga (17.55 mm), and Festival (15.21 mm). As can be understood from the CD values, the best results were obtained from the 5% lime treatment. These results suggest that the strawberry cultivars need some lime to grow strongly.

Root volume (RV) was measured by placing the roots in a measuring cylinder containing water after the plants have been removed in November 2016. After the roots are placed in the measuring cylinder, the increase in water level was measured in ml. As can be seen in Table 1, the results obtained are statistically significant ($p \leq 0.05$). The highest RV values were obtained from 7.5% lime treatment for 4 strawberry cultivars (Amiga: 54.67 ml, Festival: 33.56 ml, San Andreas: 25.58 ml, and YFL: 41.33 ml). The most effective treatment, compared with CD, was 7.5% lime treatment, while the second highest values of 5% lime treatment in Amiga (38.67 ml) and YFL (39.17 ml). The second highest values were obtained from 10% lime treatment in Festival (30.56 ml) and San Andreas (18.33 ml). The lowest values were obtained from 12.5% lime treatment in Amiga (21.33 ml), Festival (20.00 ml), and San Andreas (14.00 ml), except YFL (0%: 22.00 ml). Compared with CD, the most effective treatment on RV was 7.5% lime treatment. In addition, while the worst results in YFL (22.00 ml) were obtained from 0% lime treatment, the difference between 0% and 12.5% lime treatment was very low in Festival (respectively, 21.33 ml, and 20.00 ml) and in San Andreas (respectively, 15.42 ml, and 14.00 ml).

The crown number per plant (CNPP) was counted after the plants were removed. The results were statistically significant as shown in Table 1 ($p \leq 0.05$). The highest CNPP values were obtained from 5% lime treatment in all strawberry cultivars (Amiga: 7.42, Festival: 4.11, San Andreas: 4.25, and YFL: 6.00 pieces per plant). Second high values were obtained from 0% lime treatment in Amiga (6.44 pieces per plant), Festival (3.44 pieces per plant) and San Andreas (3.83 pieces per plant), while second high value (5.83 pieces per plant) on YFL was obtained from 7.5% lime treatment. The lowest values were obtained from 12.5% lime treatment in Amiga (2.00 pieces per plant) and San Andreas (2.17 pieces per plant, while it was obtained from 7.5% lime treatment in Festival (2.22 pieces per plant) and from 10% lime treatment in YFL (4.44 pieces per plant). If the results are compared with CD and RV, it seems to be incompatible with CD while compatible with RV. The affinity with the CD can be considered to be based on the relationship between both characters.

Table 1. Effect of lime doses on crown diameter (CD), root volume (RV), crown number per plant (CNPP), and leaf number per plant (LNPP) in Amiga, Festival, San Andreas and YFL (mean ± std. dev.).

p (0.05)		0.000	0.000	0.000	0.000

The leaf number per plant (LNPP) was counted after the plants were removed. As shown in Table 1, differences between treatments and cultivars are statistically significant ($p \leq 0.05$). The highest LNPP values were obtained from 5% lime treatment for all cultivars (Amiga: 38.50, Festival: 26.00, San Andreas: 20.58, and YFL: 41.17 pieces per plant). Second high values in Amiga (32.00 pieces per plant), and San Andreas (16.92 pieces per plant) were obtained from %0 lime treatment. However, the second-high values in Festival (15.78 pieces per plant) was obtained from 10% lime treatment, and in YFL (39.17 pieces per plant) it was obtained from 7.5% lime treatment. The lowest LNPP values were obtained from 12.5% lime treatment in Amiga (15.00 pieces per plant), Festival (12.83 pieces per plant) and San Andreas (8.17 pieces per plant), and 10% lime treatment in YFL (22.78 pieces per plant). The next lowest value in YFL cultivar (26.17 pieces per plant) was obtained from 0% lime treatment. When the obtained LNPP results were examined, it was similar to CD and CNPP, not RV. The reason for this maybe a relationship between CD and CNPP with LNPP. Relations are as follows. The increase in LNPP was due to the increase in CNPP number, and the CD was increased as a result of the increase in LNPP and CNPP numbers.

As can be seen in the previous studies, there is a need for a certain amount of lime for the growth and development of almost all plants in a healthy way, albeit vary according to species and cultivars (Schaumberger, 1990; Cutcliffe and Blatt, 1984; Aydeniz and Brohi, 1990; Inal, 1991). The results obtained from this study support previous studies. Depending on the strawberry cultivar used in this study, lime treatments have positive effects on morphological characteristics up to certain levels. While the most effective treatment was 5% lime treatment in Amiga, Festival and San Andreas on CD, CNPP and LNPP, 5% lime treatment on CD, and 7.5% lime treatment on CNPP and LNPP were effective on YFL. On the RV, 7.5% lime treatment was the most effective treatment in all cultivars. According to Schaumberger (1990), the increase in pH up to a certain level, which varies according to cultivar, has increased the content of iron in corn root and leaves. According to Aydeniz and Brohi (1990), increased lime rates increased root length, plant height and dry matter content in tomato. However, in both studies, pH level and increasing amount of lime caused negative effects. In

this study too, lime treatments over 7.5% led to negative effects on morphological characteristics. The values of CD, CNPP, and LNPP on Amiga, Festival, and San Andreas were lower in 7.5% and higher lime treatments more than 0% lime treatment. Also, RV values were lower in 10% lime treatment in Amiga and in 12.5% lime treatment in Festival and San Andreas than 0% in lime treatment While in YFL, CD CNPP, and LNPP values were lower in 10% and higher lime treatment than 0% lime treatment, RV values were higher in all treatments than control.

Fruit Characteristics

Fruits were harvested during July, August, September, and October 2016. Fruits harvested in the four-month period were calculated as the mean fruit yield per plant. As seen in Table 2, the productivity differences between treatments and cultivars are statistically significant ($p \leq 0.05$). The highest fruit yield per plant (FYPP) values were obtained from 7.5% lime treatment in Amiga (484.92 g) and Festival (411.53 g), 5% lime treatment in San Andreas (522.42 g) and 0% lime treatment in YFL (285.37 g). However, the difference between the yields obtained from 7.5% (238.49 g) and 5% (218.28 g) lime treatments and the yield obtained from 0% lime treatment in. YFL, although statistically significant, it was not so much. On the other hand, the second-high FYPP value was obtained from 0% lime treatment in Amiga (392.32 g) and San Andreas (468.90 g), while 5% for Festival (391.19 g) and 7.5% for YFL (238.49 g). The lowest FYPP values were obtained from 12.5% lime treatment for all cultivars (Amiga: 37.40 g, Festival: 79.07 g, San Andreas: 116.21 g, and YFL: 70.34 g). When tables (1 and 2) are examined, it shows that the treatment that gives the best results changes depending on the cultivar. However, it was seen that RV (Table 1) and FYPP (Table 2) values in Amiga, Festival, and YFL have largely overlapped.

After ripening, the fruits were harvested and the average fruit length (FL) was calculated. As can be seen in Table 2, the differences between the results are statistically significant ($p \leq 0.05$). The longest fruits were obtained from 12.5% (Amiga: 34.68 mm, YFL: 32.31 mm), and 7.5% (Festival: 30.56 mm, San Andreas: 35.68 mm) lime treatments. However, the shortest fruits were obtained from 0% (Amiga: 30.97 mm, Festival: 28.52 mm), 12.5% (San Andreas: 31.20 mm) and 10% (YFL: 28.78 mm) lime treatments. When the results were evaluated together with FYPP and mean fruit weight (MFW), it was seen that the differences are mostly related to the fruit load of the plants. However, the longest fruit in San Andreas (35.58 mm) was obtained from the 7.5% lime treatment which had the second-highest yield and the heaviest fruits. On the other hand, although the fruit load was low, relatively short fruit was obtained from Festival (29.08 mm) and San Andreas (31.20 mm) from 12.5% lime treatment. Taking these results into consideration, fruit load and lime treatments act together on FL.

After ripening, the diameter of the harvested fruits was measured and the average fruit width (FW) was calculated. As shown in Table 2, the differences between the results are statistically significant. The best results were obtained from different treatments depending on the cultivars. The largest fruits were obtained from 12.5% in Amiga (26.97 mm), 7.5% and 10% in Festival (26.21 mm for both treatments), 7.5% in San Andreas (27.71 mm) and 5% in YFL (25.83 mm). The second-highest fruit diameters were 7.5% in Amiga (25.34 mm), 5% in Festival (25.62 mm) and San Andreas (26.71 mm) and 12.5% in YFL (24.70 mm). The lowest values were different depending on the cultivar. The lowest values were obtained from 0% in Amiga (23.26 mm) and Festival (23.94 mm, 12.5% in San Andreas (25.31 mm) and 7.5% in YFL (22.96 mm). When the results were examined, it was seen that there are significant differences between the treatments and the cultivars. These differences appear to be due to the differences in fruit loads and the durability of the cultivars against lime.

Table 2. Effect of lime doses on fruit yield per plant (FYPP), fruit length (FS), fruit width (FW), and mean fruit weight (MFW) in Amiga, Festival, San Andreas and YFL.

p (0.05)		0.000	0.000	0.000	0.000

As fruits ripened, the harvested fruits were weighed and the mean fruit weight (MFW) was calculated. As can be seen in Table 2, the differences between treatments and cultivars were statistically significant ($p \leq 0.05$). The best results were obtained from different treatments depending on the cultivar. The MFW values of the cultivars were affected differently by the fruit load and lime treatments, as in FL and FW. The highest MFW values were obtained from 12.5% in Amiga (9.94 g), 10% in Festival (9.36 g), 7.5% in San Andreas (11.97 g) and 5% lime treatment in YFL (9.77 g). The second-highest values were obtained from 7.5% in Amiga (8.99 g) and Festival (9.14 g), 10% in San Andreas (11.37 g) and 12.5% lime treatment in YFL (9.41 g). However, the lowest values were obtained from 0% lime treatment in all cultivars (Amiga: 7.38 g, Festival: 7.45 g, and San Andreas: 10.30 g) except YFL (7.5%: 7.45 g). In addition, the next lowest MFW in San Andreas (7.92 g) was obtained from 0% lime treatment.

The lime content in the soil and the too low or too high soil pH adversely affected the vast majority of the cultivated species. Especially, the pH demand of the cultivated plant species is around 7 (Gençkan, 1992; Manga et al., 1995; Açıkgöz, 2001; Dungalic et al., 2012; Widyati-Slamet et al., 2012; Schaumberger, 1990; Cutcliffe and Blatt, 1984; Aydeniz and Brohi, 1990; İnal, 1991). Lime is a compound that must be present in agricultural soils in order to provide both pH balance and to meet the Ca needs of plants (Aydeniz, 1985; Aydeniz and Brohi, 1990; İnal, 1991). The results obtained from this study support the above-mentioned studies. In this study, lime content of the growing medium up to a certain level (5%-7.5%) increased fruit yield and quality. Depending on the cultivars, fruit yield and quality (except. YFL) of 5% and 7.5% lime treated strawberry plants were higher than 0% lime treated plants. In this study, the highest yields in Amiga and Festival were obtained from plants subjected to 7.5% lime, while those obtained from 5% lime treated plants in San Andreas. In addition, the height, diameter, and weights of the fruits obtained from the plants with high lime treatment (10% and 12.5%) were higher than those obtained from plants with low lime treatment. This was may be due to the well-fed existing fruits because of the low yield from plants that have been treated with high (especially 12.5%) lime. On the other hand, the highest yield in YFL was obtained from 0% lime treatment. However, the yield obtained from 7.5% lime treatment

was close to that obtained from 0% lime treatment. According to Cutcliffe and Blatt (1984), increasing the pH level increases the fruit yield and fruit weight in strawberry (Redcoat), while the excessive increase in pH decreases yield and fruit weight. The results obtained from this study similarly increased the yield first but decreased with the increased dose. However, MFW, FL, and FW were high in the high lime treatments in Amiga and Festival which had low fruit load. In San Andreas, the highest values were found in 7.5% lime treatment. This seems to be due to the relatively high yield at high lime treatments. On the other hand, in the YFL, the best values were obtained from different treatments, whereas 5% and 7.5% lime treatment were more effective in terms of fruit characteristics. Besides, the sizes of the fruits obtained from 5% and 7.5% lime treatments in all cultivars (except in FW in YFL) were higher than the fruits obtained from 0% lime treated plants.

Conclusions

In this study, San Andreas was the most resistant cultivar to high lime doses among the four cultivars studied. The yield of San Andreas in 10% lime treatment was considerably higher than other cultivars. Moreover, San Andreas has been the most productive cultivar in all treatments except 7.5%. On the other hand, the highest yield of Amiga and Festival was obtained by 7.5% lime treatment. However, the yields of cultivars except San Andreas and Festival have decreased considerably at 10% lime treatment. In 12.5% lime treatment, the yields of all cultivars decreased dramatically.

According to the results, the following conclusions can be drawn. First, it may be beneficial for the soil to contain some lime so that the pH balance can be maintained and the calcium needs of the plants can be met. However, the amount required varies by species and cultivars. Second, the tolerance of strawberry cultivars to different lime levels varies. In this study, the number of cultivars used and the doses of lime were limited. Determining the maximum lime and pH levels that strawberry cultivars can tolerate more extensive studies will contribute to multicultural diversity in agriculture.

REMOTE SENSING TECHNIQUES FOR RESEARCH AND CLASSIFICATION OF THE PHOSPHORUS AMOUNT REQUIRED FOR SUGAR BEET PLANT

Rutkay ATUN*, Önder GÜRSOY

Department of Geomatics Engineering, Cumhuriyet University, Turkey
*Corresponding author: ratun@cumhuriyet.edu.tr

Abstract

Remote sensing and its terrestrial components provide practical and effective solutions in agricultural applications. Remote sensing in such areas as plant stress, irrigation, fertilization and investigation of chlorophyll content does not only provide a quick solution, but also provides precision agriculture with high accuracy. One of these application areas is to investigate the proper amount of fertilizers for plant health and development. Phosphorus was used as fertilizer in this study. Phosphorus is an element that people, plants and animals must take, however, phosphorus deficiency is a common occurrence. In addition, excessive amounts of phosphorus could be harmful to both plant health and to the ecosystem. Therefore, it is significant to apply the correct amount of phosphorus fertilizer in agriculture. In this study, an agricultural land in Sivas province was divided into three parts and phosphorus fertilizer was introduced at three different doses (0 kg P ha^{-1}, 150 kg P ha^{-1} and 300 kg P ha^{-1}) were, then sugar beet was planted to these areas. After the plants developed, spectroradiometer measurements were made on their leaves to obtain the spectral signatures of the plants in each phosphorus group. Spectroradiometer measurements were performed simultaneously with Sentinel 2 satellite transition. A spectral classification was carried out by resampling the reference spectra from the terrestrial measurements to the Sentinel 2 satellite band intervals. As a result, the growth of plants was monitored and sugar beet, which was treated with different amounts of phosphorus fertilizer, could be detected by using a satellite image.

Keywords: *Remote sensing, Spectral classification, Sugar beet, Phosphorus.*

Introduction

The use of remote sensing technology and its terrestrial components is increasing day by day. The accuracy of remote sensing technology is increasing accordingly along with the development of the technology. Remote sensing provides quick, easy and fast access to information. The areas of use of remote sensing vary in such fields as geology, mining, forestry, hydrology, mapping, construction, military industry, and so on. One of the most frequently used areas of remote sensing is agriculture (Tilling *et al.*, 2007*;* Wei *et al.*, 2008*;* Meggio *et al.*, 2010*;* Ramoelo *et al.*, 2015*;* Caturegli *et al.*, 2015*;* Argyrokastritis *et al.*, 2015). Managing and implementing agricultural policies sensitively is utmost importance for the economy of a country. Managing agriculture agreeable is one of the keys to sustainable development as well. Remote sensing, on the other hand, makes it possible to apply agriculture well due to its technological advantages.

Sugar beet is an important agricultural product grown in Turkey. Turkey ranks 5th in world production of sugar beet in 2008, according to statistics (Topak *et al.*, 2010). Sugar beet has a wide range of uses. It covers a large part of the sugar production in the country and is also used as animal feed. In addition, it is used in the production of alcohol and spirit.

Fertilizer is an extremely important factor for the development of plants. Some elements are limited in soil depending on the structure of it. Therefore, they must be given to the soil as fertilizer. Phosphorus is an element, one of this that plants must absolutely take. However,

excessive amounts of phosphorus can be harmful to both plant and soil. Therefore, applying the right amount of phosphorus fertilizer is extremely important for both plant and ecosystem. In this study, phosphorus fertilization was applied to sugar beet plant in different doses. Then, the development of the sugar beets were monitored according to the different amounts of fertilizer. As a result, sugar beets applied different amounts of fertilizer were detected by spectral classification through satellite image and terrestrial remote sensing measurement data.

Material and Methods

A zone of sugar beet was planted in a field belonging to Ulaş area (figure 1) of Sivas city as a study area, within the scope of the study. It was determined that the level of soil clay, limey and salinity used in the study is low. Valentina was used as a type of sugar beet.

Figure 1. Study area

European Space Agency's Sentinel 2 sensor was utilized as a satellite image (Clevers and Gitelson, 2013). Radiometric and atmospheric corrections were made to remove atmospheric and radiometric defects on the image.

Three different phosphorus fertilizers were applied to the study area: 0 kg P ha^{-1}, 150 kg P ha^{-1} and 300 kg P ha^{-1}. Then, spectroradiometer measurements were made on the leaves when the sugar beets grown in order to obtain end members required for spectral classification. Spectroradiometer measurements reflectance values were then resampled to Sentinel 2 band intervals in order to use them to spectral classification.

Results and Discussion

As a result of spectroradiometer measurements, it was determined in which region of the electromagnetic spectrum of the sugar beet that the phosphorus fertilization was applied in different doses. A steady change is observed between 2000 and 2500 nanometres depending on the amount of phosphorus, but no linearity exists in other regions. As a result of the

spectral classification, different amounts of phosphorus fertilization treated areas could be detected on the satellite image (figure 2). The Sentinel 2 satellite, on the other hand, shows the productivity and usability of agricultural applications in remote sensing. In order to increase the accuracy of the study, it has been shown that it is necessary to integrate the terrestrial remote sensing measurement data with the satellite image.

Because the spatial resolution of the satellite image used in classification is limited, classification result does not overlap with the resultant phosphorus dose in some regions where phosphorus is applied in different amounts. Using a higher resolution satellite image will improve classification accuracy.

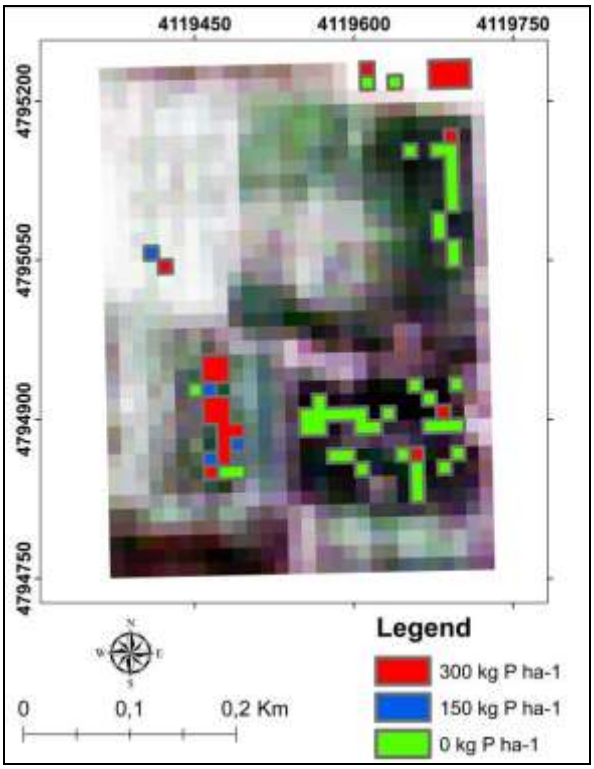

Figure 2. Result of spectral classification on Sentinel 2 image

Conclusions

As a result of the study, it was understood that how fast, practical and accurate results of remote sensing in agricultural applications. It has been seen that the study done is a basis for future work. Fertilizer quantities applied in very large areas can also be detected on the satellite image by applying the technique to different zones. Thus, sustainable development can be achieved while the manageability of sensitive agricultural policies is increased.

Abstract

Sunflower (Helianthus annuus L.) is cultivated in many countries of the world due to its high adaptability and is being used for various purposes. It is primarily produced for sunflower, confectionery, ornamental plant, fodder, and other purposes for agriculture in order to obtain oil. As a confectionery production and consumption have an economy that can not be underestimated. In this respect, there is a need to develop varieties of confectionery sunflower. Approximately for 10 years, 36 lines have been selected by single plant selection and have the ability to be combined with each other. In the study, promising lines in the third year of the self-fertilization phase were used. In each line, 10 plants were isolated before flowering and prevented from taking polen from the outside. Results of the study were shared in 2017. Characteristics discussed: self-fertilization rate, plant height, disc diameter, disc shape, full achene, empty achene, achene length and achene width. Significant changes were observed in the plant height and table size in the lines due to depression of the self-fertilization. In addition, deformations were detected in the shape of disc. An increase in the rate of full achene in the subsequent selfing generations has been observed as a positive development.

Keywords: *Sunflower, breeding, confectionery, selection.*

Introduction

Today, sunflower is used to meet the need for a large amount of cooking oil. In some countries, varieties of oil seed sunflowers as well as snack varieties are produced (Lofgren, 1978). Seeds of these varieties are rich in nutrients and are mixed with salt, butter, and honey to make confectionery, added as a condiment on vegetables, fish, meat and salads, also consumed in the form of cookies in roasted or unroasted (Millete, 1974).

Sunflower production in Turkey, Black Sea and Thrace-Marmara, Aegean, Central Anatolia and Çukurova are made. It can grow in dry or wet conditions in almost every region of Turkey. With the adaptation of the sunflower being good, our sowing areas have remained at 500-600 thousand hectares. Turkey confectionary sunflower production is 180 thousand tons and yield is 1550 kg per hectare (Tüik, 2015).

Sunflower should use as appetizer in Turkey, as well as is quite common in the world's different countries, is the most consumed cookies by people in many countries. Sunflower has long been used by humans as a snack and has been used in more than a hundred food types around the world, such as bread, pastry, ice cream, chocolate, cookies etc. sunflower seeds are used internally (Lofgren, 1997). Although the sunflower is described separately as oil and confectionary, the statistics of the confectionary are not given much in the country agricultural organizations (OECD, FAO, ISA etc.). Confectionary sunflower cultivation in the province made economic sense in Turkey; Kahramanmaraş, Elazığ, Ankara, Aksaray, Balıkesir, Bursa, Uşak, Burdur, Yozgat, Kırşehir, Amasya, Çorum, Erzurum, Kayseri, Iğdır, Isparta, Eskişehir and Tekirdağ and Edirne (Tan, 2011). The seeds used are mostly known as open-dusted village populations (Tan, 2011), but in recent years certified varieties have been used. Certified varieties used as seeds have been rehabilitated abroad (Avesa Çrz 2012,

Marker, Confeta CL and Shelly), as well as varieties of domestic confectionery sunflowers that have been improved in our country (Çiğdem 1, Palancı 1, 09 TR Ç 004, Çetinbey ve İnegöl alası).

Generally, according to the physical appearance in the confectionary sunflower grown in the Central and Eastern Anatolia provinces; Alaca, Cyprus, İnegöl and so on. The use of village populations, the majority of which is derived from the unit area due to the cultivation of the vast majority in arid conditions, is much lower than the type of oil used in hybrid varieties (Kaya, 2004). According to most researchers; confectionery sunflower type; low oil content should contain high protein. In addition, low shell ratio and wide grain size are also desirable characteristics of snack types (Kaya at al., 2008; Hladni et al., 2011).

In this study, it is aimed to purify the varieties of confectionery sunflower with the characteristics demanded by the consumer and high adaptation ability. In this way, it will be possible to find out the types that will respond to the needs of the country and to register them or to develop advanced stages. In accordance with this purpose; The breeding trial is ongoing. The results obtained in 2017 are shared between lines that are self-healing. .

Material and Methods

The study was conducted in Central and Eastern Anatolia to purify genotypes collected in 2002 and reduced to 13 by selection over a period of 10 years. In the purification study, the plants of 13 confectionary sunflower genotypes (12, 18, 27, 28, 50, 77, 84, 85, 87, 90, 93, 100, 110) were isolated to prevent pollen from the outside and the plant was self-fertilized. Thus, in addition to the purification of the line, the rate of self-fertilization of lines, which is an important feature for sunflower breeding, has also been determined. 13 lines obtained by single plant selection were sown in May 2017 as a single line. The necessary maintenance procedures (hoeing, irrigation and fertilization) were carried out in accordance with the procedure. Prior to flowering (tabla formation), the plant was forced to fertilize itself by passing 5 herbal isolation bags randomly selected in each order. After the seed formation was completed, the insulation bags were removed. The tables belonging to each line were harvested and necessary measurement and counting processes were performed. The results of 13 lines which have been successful in self-fertilization were evaluated.

In genotypes that achieve self-success;

- self-fertilization rate (%),
- plant height (cm),
- full achene (unit),
- empty achene (unit)
- disc diameter (cm),
- disc shape,
- achene length (mm) and
- achene width (mm) have been examined.

Results and Discussion

The results obtained and the evaluation of the statistics are given in Table 1. When examining 13 lines taken at the stage of self-healing, with the highest rate of self-fertilization belonging to the 77th line with 93.5%. In descending order, 87 lines (92.9%), 84 lines (91.0%) and 93 line (90.2%) were observed. Snow et al (1998) reported; the rate of self-fertilization in sunflower ranges between 15-95%, on average, self-fertilization rate is 68%.

therefore, the lines with a self-fertilization rate below 68% will be disabled. The lines of 12 and 90 which have more than 68% value in themselves have been found promising. When examined in terms of disc diameter; It is determined that the 18th line forms larger tables than

the other lines. The main factor in this study is the selection of lines with high self-fertilization rates. However, the large diameter of the table is important for productivity. On the other hand, the achene length is the reason why consumers prefer it. When all these issues are dealt with, 77 is the front line. However, lines 84 and 87 appear to be good parental candidates for further breeding processes.

Table 1. Evaluating the results and statistics obtained in the study

Line Number	Replications	Full achene (unit)	Empty achene (unit)	Self-fertilization rate (%)	Disc shape	Plant height (cm)	Disc diameter (cm)	Achene length (mm)	Achene width (mm)

Conclusion

When examined in terms of disc diameter; lines 12, 18, 77 and 100, in terms of achene length; lines 12, 18, 77 and 85, in terms of the number of full achene; lines 28, 77, 87, 90 and 93 are prominent. On the other hand, in terms of self fertilization rate, which is the most important criterion of this study; the lines 12, 77, 84, 87, 90 and 93 were above the specified level (68%). It has been decided that lines 12, 77, 84, 87, 90 and 93 with overall performance ability should be included in the hybridization program.

THE EFFECTS OF 2,4-D AND BAP ON *IN VITRO* SOMATIC EMBRYOGENESIS IN QUINOA (*CHENOPODIUM QUINOA* WILLD.)

Sevil SAĞLAM YILMAZ[1*], Şeyma DOĞANCI[2]

Abstract

Chenopodium quinoa Willd. (Quinoa) is a pseudocereal, an annual broad-leaved plant, 1–2 m height with deep penetrating roots and can be cultivated from sea level up to an altitude of 3800 m. The plant shows tolerance to frost, salinity and drought, and has the ability to grow on marginal soil conditions. Also, Quinoa is highly nutritious due to its outstanding protein quality and wide range of minerals and vitamins. The grain protein is rich in amino acids like lysine and methionine that are deficient in many other cereals. Somatic embryogenesis is the main plant tissue culture method used in *in vitro* mass production, synthetic seed production, and gene transformation. The effect of different concentrations of BAP (6-benzylaminopurine)-2,4-D (2,4-dichlorophenoxyaceticacid) on *in vitro* somatic embryogenesis from shoot apex and stem explants of quinoa was studied. The most commonly used auxin type to promote callus formation and somatic embryogenesis was 2,4-D in previous studies. Highest percentage of seed germination (100%) was obtained in full strength MS medium on 5% NaOCl application for 5-10 minutes. Best embryonic callus induction (100%) was observed on MS medium supplemented with 0.5 mg/l 2,4-D from shoot apex explants. The callus which was produced in this treatment was compact and of high quality for somatic embryogenesis. This work can be used to develop the virus-free and saponin level reduced cultivars on quinoa.

Keywords: *Chenopodium quinoa, Quinoa, somatic embryogenesis, 2,4-D, BAP*.

Introduction

Quinoa (*Chenopodium quinoa* Willd.) is a dicotyledon, annual, herbaceous plant from the goosefoot (*Chenopodiaceae*) family and adapt well to cold and dry weather conditions. Although quinoa can grow in saline, alkaline, and dry soils, quinoa plants grown in saline soils and dry climate conditions have a high yield, albeit their seeds are rich in saponin. The origin center of quinoa is the Andean Mountains region in South America (Weber, 1978).

Recent advances in *in vitro* culture methods give rise to the possibility of more effective rehabilitation programs. High-yielding, disease-resistant, saponin-free, and lysine-rich quinoa cultivars can be developed using *in vitro* methods. Homozygous plants are also of advantage in obtaining saponin-rich lines, which are used for pharmaceutical purposes. Haploids with homozygous genes are either produced by anthers or stimulated by direct embryogenesis and haploid callus formation (Nitsch, 1977). The use of saponins in quinoa as compounds with pharmacological properties in agriculture, medicine, and industry should not be overlooked.

The number of the studies focusing on the *in vitro* methods applied to the *Chenopodiaceae* family is limited. Somatic embryogenesis is the main plant tissue culture method used in clonal propagation, synthetic seed production, and gene transformation.

This study investigated the effects of the alone and combined applications of 2,4-D and BAP to the explants derived from shoot apices and stems on somatic embryogenesis.

Material and Methods

Limtar Red quinoa cultivar was used as the plant material for research purposes. Seeds, harvested in 2016, were procured from the Central Directorate of Seed Registration and Certification, Ankara, Turkey. The study was carried out in 2016-2017 in the Plant Tissue Culture Laboratory of the Agricultural Biotechnology Department of the Ahi Evran University Agriculture Faculty, Ahi Evran University/Turkey.

In the trials, different ratios and combinations of 2,4-D and BAP was added to MS (Murashige and Skoog, 1962), 3% saccharose, and 0.5% plant agar were used. pH to 5.7±0.1 using either 1N NaOH or 1N HCl, the medium was sterilized 20 minutes by keeping at 121^{o}C under 105 kPa pressure. All cultures were kept under a photoperiod of 16 h and in a climate chamber at 24±1 $^{\circ}$C. In the somatic embryogenesis trials for quinoa, 2,4-D and BAP were used. Stock solutions at 1 mg/l concentration were prepared for all growth regulators used in the study, and different doses of a growth regulator alone and its combinations with other growth regulators were added into the MS medium. For the stock solution of 2,4- D, 1-2 drops of ethyl alcohol (EtOH), for the stock solution of BAP, 1-2 drops of 1 N NaOH were used as dissolvers; then, the solutions were completed using pure water, and were vortexed to obtain homogenous mixtures. The stock solutions were transferred to falcon tubes and kept in a refrigerator at 4°C, and re-prepared when necessary.

The effect of 2,4-D and BAP on somatic embryogenesis from the explants derived from shoot apices and stems

To determine the effect of different 2,4-D concentrations on *in vitro* somatic embryogenesis 0.50, 1.00, 1.50, and 2.00 mg/l concentrations of 2,4-D were used and the growth regulator free medium was used as the control. Shoot apices and stem parts from *in vitro* germinated seedlings were used as explants. Cultures were observed after 14 days for embryonic callus formation. The most commonly used auxin type to promote callus formation and somatic embryogenesis was 2,4-D in several of the previous studies (Burbulis et al., 2007). In a study on somatic embryo culture for quinoa, hypocotyl explants were sown on0.45 mg/l 2,4-D-added MS mediumand callus formation was observed after 2 weeks; somatic embryo development was observed when calluses were also sown on a 2,4-D-free MS medium (Eisa et al., 2004).

In another set of experiments to determine the combined effects of 2,4-D and BAP on *in vitro* somatic embryogenesis of the quinoa seeds, 0.5 mg/l 2,4-D and 0.50, 1.00, 1.50, and 2.00 mg/l concentrations of BAP were used with the growth regulator-free medium as the control. Cultures with shoot apex and stem explants were observed after 14 days.

All trials were carried out following the Randomized Blocks Experimental Design. Each treatment was repeated three times with magenta vessels (GA-7) containing 5 explants in each. The data were analyzed using the "SPSS for Windows 24" computer software and the differences among means were compared using the Duncan test. Prior the statistical analysis, values in percentages were converted to arcsine values (Snedecor and Cochran 1967).

Results and Discussion

Stem and shoot apex explants were placed in 0.50, 1.00, 1.50, and 2.00 mg/l 2,4-D-containing MS mediums to promote embryonic callus formation, and the statistical analysis of the callus formation ratios was performed and the results were compared to each other. The difference between the applications was significant at the level of 0.05. Results are summerized in Table 1, hundred percent (100%) callus formation was observed in the shoot apex explant in the presence of 0.50 and 1.00 mg/l 2,4-D, while 100% callus formation was observed in the stem explant with 0.50, 1.00, and 2.00 mg/l 2,4-D applications. Calli produced are embryonic and the callus formation in the shoot apices decreased with the increasing doses of 2,4-D.

Table 1. Ratio (%) of callus formation from shoot apex and stem explants in the Limtar Red quinoa cultivar

2,4-D (mg/l)	(%) Callus formation **	
	Shoot apex	Stem
0.50	100.00a	100.00a
1.00	100.00a	100.00a
1.50	93.33b	86.67b
2.00	80.00c	100.00a

** There was a significant difference at the level of 0.05 between the means with different letters in the same column.

Figure 1. The initial stage of somatic embryogenesis in the shoot apex explants of quinoa after 2 weeks

Figure 1 shows the visible condition of the explants kept in different doses of 2,4-D for 2 weeks. After 4 weeks, the calluses were transferred to MSO mediums to continue embryonic callus formation. All embryonic stages were observed in the calluses in these mediums.
Statistical analysis revealed that there is a significant difference in the callus formation ratios in the Limtar Red quinoa cultivars at the level of 0.05. With 40%, highest callus formation in the shoot apex explant was observed in the presence of 0.50 mg/l 2,4-D and 2.00 mg/l BAP, while highest callus formation in the stem explant was observed in the presence of 0.50 mg/l 2,4-D and 1.00 mg/l BAP (Table 2.). The increasing amounts of BAP decreased the callus formation in stem explants. Figure 2. shows the callus formation from the stem explants of the Limtar Red quinoa cultivar in the 0.50 mg/l 2,4-D and 1.00 mg/l BAP-containing nutrient medium. Hesami and Daneshvar, (2016) investigated the callus formation from the hypocotyl explant derived from quinoa in different MS medium concentrations and observed the highest callus formation as 93.33% in the 0.5 mg/l 2,4-D and 0.05 mg/l BAP-added MS medium.

Table 2. Callus formation ratio in the shoot apex and stem explants of the Limtar Red quinoa cultivar in 0.50 mg/l 2,4-D and different doses of BAP (%)

Treatment		(%) Callus formation*	
2,4-D (mg/l)	BAP (mg/l)	Shoot apex	Stem
0.50	0.50	13.33a	6.67b
0.50	1.00	6.67b	40.00a
0.50	1.50	26.70a	6.67b
0.50	2.00	40.00a	6.67b

* There was a significant difference at the level of 0.05 between the means with different letters in the same column.

Figure 2. Callus formation from the stem explants of the Limtar Red quinoa cultivar in the presence of 0.50 mg/l 2,4-D and 1.00 mg/l BAP in MS medium

The co-examination of the data and Table 1 showed that although the use of 0.5 mg/l 2,4-D alone promoted 100% callus formation both in the shoot apex explant and in the stem explant, the combined use of 2,4-D with BAP resulted in a decrease in the callus formation ratios in both explant sources.

Conclusion

The most commonly used auxin to promote embryogenesis is 2,4- dichlorophenoxyacetic acid, which is usually added into 2,4-D nutrient medium at ratiosranging from 0.5 mg/l to 2.0 mg/l. If somatic cells are cultured in 2,4-D-containing medium in the first culture stage, and then, transferred to a new auxin-free medium, they develop the ability to produce embryos. With 100%, the highest callus formations in the shoot apex and stem explants were observed in the control group, and in0.50 mg/l and 1.00 mg/l doses of 2,4-D. After 45 days in the 0.5 mg/l 2,4-D and 1.00 mg/l BAP-added culture, callus formation and red coloring were observed in stem explants, which led to the conclusion that BAP addition at high concentrations caused color changes, and coloring in red tones was attributed to saponin.

Scientific knowledge on quinoa species is still insufficient, albeit widespread popularity of quinoa among consumers. Obtaining clones with low saponin content is an important

rehabilitation goal, and developing cultivars that will not regain their saponin production capacities should be emphasized. This can be obtained through the improvement of genetic properties. The results of this study will serve as an important foundation for this goal.

Abstract

Birdsfoot trefoil a series of abiotic stress adaptation is an important component of grassland ecosystems and natural life, apart from producing feed in restricted areas in the direction of environment. One of the solutions for generalize the birdsfoot trefoil breeding is to produce quality seeds in sufficient quantity. This research was conducted to determine the effects of various row spacing (20,40,60 and 80cm) and seeding rate (5,10,15 and 20 kgha-1) on birdsfoot trefoil (cultivar candidate) seed yield and quality components. The experiment was conducted at the Tokat Agricultural Research Institute, using a randomized complete block split-plot design with three replications in 2016-2017 growing season. Research result; while the row spacing and seed amount applications had significant influences on the seed yield and the weight of thousand seeds for the first harvest and on the germination rate for the second, they didn't have a statistically relevant effect on other parameters. The interaction between row spacing and seed rate had no correlation except for the seed yield performance of the first harvest. Seed yield was to increase with narrowest spacing and increased seed rate. Highest yield for both harvests (226.1 and 85.4 kgha-1 respectively) were achieved with 40 cm row spacing and 10 and 15 kgha-1[1] seed amounts. Highest weight of 1000 seeds performance was achieved with 40 cm row spacing with 5-10 kgha-1 seed rate, while the highest germination rate was found to occur in 40-60 cm row spacing with 10 kgha^{-1} seed rate.

Keywords: *Birdsfoot trefoil, Sowing frequency, Thousand seed weight, Seed germination,*

Introduction

Birdsfoot trefoil *(Lotus corniculatus* L.), is a short to medium-lived, perennial special legume plant. Birdsfoot trefoil is with a high protein content (15-28% DM) and is a valuable forage that can be grazed or cut for hay or silage, and does not cause bloat in ruminants. The condensed tannins in birdsfoot trefoil elicit reductions in CH4 emissions and urinary N in dairy cattle (Williams et al., 2011). These tannins Unlike other legumes prevent bloat (by reducing methane and ammonia emissions), together with anthelminthic activity in ruminants (Hannaway et al., 2004; Waghorn, 2008). It is also helpful for erosion control, revegetation and as a wildlife habitat (Bush, 2002; FAO, 2014). Its flowers produce abundant and concentrated nectar and it is considered a valuable honey plant (Canpolin, 2012). Birdsfoot trefoil is an N-fixing legume, takes significant place in sustainable agricultural and organic production (Tomić, 2007). It is tolerant of wet acidic soil (pH = 4.5) and has some drought tolerance. Birdsfoot trefoil can withstand some soil salinity. It thrives in places where alfalfa and other forage legumes cannot grow because of soil acidity and moisture (FAO, 2014; Hannaway et al., 2004).

Potential seed yield of the plant is estimated at 1200 kg ha-1, while the average yields on the global level are below 200 kg ha-1 (Turkington et Franco, 1980; Gullien, 2007).

Regarding the seed cultivation performance of the birdsfoot trefoil, (Winch et al.1985) report that 1000 seed weight for the plant is between 0,78-1,26 grams, while seed germination rate

varies between 43-80%. Stevovich et al. (2013) have reported that the Rocco type of the foil has increased seed yield compared to the K-37 and Zora types (408 kg ha^{-1} against 85 kg ha^{-1} and 54 kg ha^{-1}, respectively), while the 1000 seed weight for the plant varies between 1.22-1.24 grams. Pankiw et al. (1977) have achieved the highest seed yield for three consecutive years (537 kg/ha) using 15 cm row spacing and 4.5-9 kg/ha seed rates (for 443-456 kg/ha yield, respectively). Gatarić et al. (1990), have achieved the highest seed yield with 60 cm row spacing and 12 kg/ha seed rate (1^{st} part 311 kg/ha, 2^{nd} part 192 kg/ha). In his studies, (Petrović, 2011) has found that the lowest seed yield (97.1 kg/ha) was obtained with 12.5 cm row spacing, while the highest (155.9 kg/ha) was achieved with 25 and 50 cm rows (155.7 kg/ha) using the highest seed rate norm available (8kg/ha). Ayres et al. (2008), on the other hand, report 1000 seed weight for the plant between 0.72-1.17 grams.

The difficulty of obtaining consistently high yields of seeds has limited the use of the bird's foot trefoil significantly: the beans are easily crumbled and the seeds often spill over and are lost (Fairey, 1994). Significant losses occur during the seed harvesting of bird's foot trefoil, causing a varied seed yield of up to 85% (Winch et al., 1985). To test the plant's seed yield, McGrew et al. (1986) have conducted a research in three separate locations and have detected that genotype and environment had significant interactions between each other. For that reason, the researchers have concluded that the seed yield tests have to be conducted in the location where the plant is commercially cultivated. Steiner et al. (1995) have reported that the seed yield of perennial leguminous plants is determined primarily by the plant's genetic basis, which was followed by environment conditions, initial harvest time, presence of insects & pollinators, and the interaction between genotype and environment.

The most important condition for more widespread birdsfoot trefoil cultivation is to be able to obtain proper amounts of high-quality seeds(Petrovic 2011). It is also known that plant spacing has significant effects on seed yield and quality. Very high or very low plant spacing may cause adverse effects like diseases and increased pressure from other plants. Many cultivators are seeking production guidelines that will help them create production programs to maximize their yields and to achieve agricultural and commercial success (Ekiz et al.2009). Regarding the effects of the plant population density on the birdsfoot trefoil seed production and quality is little information exists on for our country. Furthermore, since the plant is perennial, determining the optimum density is a complicated process.

This study aims to determine the optimum row spacing and seeding rate in order to obtain maximized high-quality seed yield and net gains, and to gain insight on the effects of plant population on the seed yield and quality components of birdsfoot trefoil. The results obtained from this study can be used as scientific and practical guidelines to increase birdsfoot trefoil cultivation and to improve high-quality roughage production.

Material and Methods

The research took place under the agro-ecologic conditions of Central Black Sea Region of Turkey within the province of Tokat, in the Central Black Sea Transition Zone Agricultural Research Institute fields, during the 2016-2017 cultivation periods. The coordinates for the research field are 40° 18' latitude and 36° 34' longitude and has an altitude of 585 meters.

The soil analysis of the field has revealed the following properties: the soil had medium-heavy (clayey-loamy) nature, salinity was almost non-existent (0.028%), pH was slightly alkaline (pH 7.6), and it was poor in plant-consumable phosphor (P: 13.5 kg/ha) and organic materials (N: 9.5 kg/ha). On the other hand, it had medium amounts of lime ($CaCO_3$:77,0 kg/ha), and ample amounts of potassium (K_2O: 812,9 kg/ha).

The regional climate of the Tokat district carries the marks of a transition zone between the steppe climate of the Central Anatolia region and the Black Sea region. There was no significant average temperature variation for the years of 2016 and 2017 in which the study

was conducted, but the year of 2017 had significantly less rainfall during the growth period compared to previous years. The minimum and maximum temperatures were also considerably lower and higher compared to previous years as well, respectively. Table 1 below contains some of the climate data for the study area, spanning the years the study took place.

Table 1. Temperature and rainfall values of the experimental years in and long-term average (1929- 2017) in TOKAT*.

Month	Highest monthly temperature m (°C)			Lowest monthly temperature mean (°C)			Raining monthly averages (mm)

*Data source: The General Directorate of State Hidraulic Works. (1929- 2017)

In this study, cultivar candidate improved for birdsfoot trefoil was used as plant material. Genotype is of erect or semi-erect growth type. It has a forage yield of 32.0/51.0 tons/ha under various conditions, while it has a seed yield that varies between 287.0 and 347.0 kg/ha. The crude protein content is around 18.5 to 19.7%, while the Acid detergent fibre (ADF) content is 31.1% and Neutral detergent fibre (NDF) 39.9 % (Karadağ et al.,2016; Çınar et al.2016).

The experiment was conducted at using a randomized complete block split-plot design with three replications. Before the sowing, 200 kg ha- 1 N18P46K0 fertilizer was applied to the soil. Weed control was done hand hoe and mechanically on two occasions. Plants were grown without irrigation. İn research main plot was four rows spacing (20,40, 60 and 80 cm) and sub plots were different seeding rate (5, 10, 15 and 20 kg seed ha-1) were tested.

The seed planting was carried out with a row seeding machine at a depth of 1.0-1.5 cm, and on March 12, 2016.

Seed yield and quality components were determined from the first cut in the year of the second growing season. The following components of quality were determined on the laboratory: seed yield, seed germination rate, and of thousand seed weight. Seed yield was determined during the stage where 70 to 80% of the pods were turning brown. Half of every sub-parcel was harvested twice in 5 to 7 cm height using a parcel harvester (first harvest in 21 July, second in 6 September, 2017). All the harvested plant materials were gathered and laid to rest in an air-dry environment for 4 weeks. The parcels were then blending using a parcel thresher machine. Every seed sample was sifted using 1.0 to 2.0 mm sifters and cleaned using a portable fan set. The obtained seed weights were recorded in kg/ha format.

The seed germination rates (%) were calculated using the internationally accepted methodology (ISTA 1993), where 50 seeds were germinated on petri dishes over germination papers in four iterations in 25-28 ^{0}C for 4-7 days and were counted. 1000 seed weight was determined counting 100 seeds 4 times over (ISTA 1993).
The research data were analyzed by the analysis of variance of the two-factorial trial using JMP software. The significance of differences in mean values was tested by LSD test.

Results and discussion

Seed yield

As can be seen in Table 2, the seed yield increases as the row spacing is reduced and seeding rate is increased, and the difference is statistically relevant. The highest yield was achieved with 40 cm row spacing, while the lowest was achieved with 60 cm. For the different seeding rate applications, the highest yield was achieved with 10.0 kg/ha for both harvests, and in 15.0 kg/ha which is within the same statistical group.

Table 2. Comparing yield component averages and birdsfoot trefoil seed yield and row spacing and seed rate treatments of during experimental year.

Row spacing A	Seed yield (kg ha-1)		Thousand seed weight		Seed germination rate	
	I. cut	II.cut	I. cut	II.cut	I. cut	II.cut

AXB	3.72**	ns	ns	ns	ns	ns

Values followed by different letters within columns are significantly different ($P < 0.05$) according to the LSD test *F test signifi cant at $P \leq 0.05$; **F test significant at $P \leq 0.01$; NS = not significant

The lowest seed yield was achieved with 5.0 kg/ha seeding rate. The seed yield values with regards to row spacing – seeding rate interaction varied between 132.4-281.7 kg/ha, while the highest seed yield was achieved in the 40 cm row spacing with 10.0 kg/ha seeding rate, where the yield amount was 281.7 kg/ha.
The results of our study are in compliance with the results of many previous studies (Turkington and Franco, 1980; Gullien, 2007; Fairey and Smith, 1999; Vučkovic et al., 1997).

Thousand-Seed Weight

Thousand-seed weight is an important seed quality component indicating seed size and seed fill. The results of our study show that the row spacing has no statistically relevant influence over the seed weight, while seeding rate was found to be the primary factor for the first harvest and had no effect for the second. The highest average 1000 seed weight for both

harvests (1.08 and 0.71 g, respectively) were achieved with 40 cm row spacing, and with 5.0 kg/ha seeding rate for first harvest, and with 10.0 kg/ha seeding rate for the second (Table 2). While our results are in line with the findings of Ayres et al. (2008), Vinch et al. (1985), and Gatarić et al. (1990), they are lower compared to the findings of Stevovich et al. (2013)

Seed Germination Rate

The row spacing was effective on the germination rate for the 2nd harvest in a statistically relevant manner, while the seeding rate and row spacing and seed rate interaction were not effective for other harvests. Average seed germination rate was lower for the first harvest and was found to be between 62.6-68.3%, while it increased to 71.4-79.8% for the second (Table 2). This change can be attributed to changes in temperature and other environmental conditions and may also be influenced by the seed quality and the time of harvest.

Conclusions

In this study, the data for the second year of cultivation (2017) were evaluated, and it was found that the seed yield increased with the reduced row spacing, and increased seeding rate. This study shows that 20-40 cm row spacing and 10.0 -15.0 kg/ha seeding rate is enough to obtain proper seed yield for the bird's foot trefoil in the Central Black Sea Transition Region agro-ecologic conditions, and conditions that are similar to it. Furthermore, the results of this test also indicate that close row spacing (20-40 cm) has positive effects on weed control.

Abstract

Zamioculcas zamiifolia Engl. (ZZ), native of Eastern Africa, is a stem-less herbaceous monocotyledon belonging to Family Araceae. It produces attractive dark green and glossy foliage with succulent rhizomes at the base. This foliage ornamental is gaining popularity as an indoor plant showing best performance even under reduced light and restricted water. ZZ plants are propagated vegetatively using leaflets. Large scale multiplication is very expensive due to its slow growth and low multiplication rate. The use of growth regulators in the propagation of ZZ plants has been attempted to address the issue. Mature leaflets collected from healthy stock plants were treated with rooting hormones *viz*: IAA, IBA and NAA at 1000, 2000, 3000, 4000 and 5000 ppm. IAA at 2000 ppm was found to initiate rhizomes in 30 days and 30% of the treated leaflets produced plantlets in five months. IBA at 2000 and 3000 ppm also resulted in initiation of rhizome in 30 days. However, the number of plantlets formed was less (12.5%). Early tuberization and shoot initiation occurred in three weeks and subsequently plantlet formation was observed in twelve weeks at 3000 ppm NAA and maximum shoot length of 11.42 cm at 5000 ppm. Among the growth regulators tested, NAA 3000 ppm gave promising results in terms of time taken for initiation of tubers, tuberization and formation of new shoots and its employability in nursery production. The findings of the research are useful for largescale and faster multiplication of ZZ plant in nursery production to meet the demand.

Keywords: *ZZ, propagation, IAA, NAA, IBA.*

Introduction

Zamioculcas zamiifolia Engl. (ZZ), is stem-less herbaceous monocotyledonous plant belonging to family Araceae (Feng,2006; Wong, 2009). The plant is sub-erect, evergreen perennial, native to Eastern Africa. It produces succulent rhizomes at the base of attractive dark green and glossy foliage. (Lopez, *et al.*, 2009). The plant consists of a large tuber and a short, thick underground stem from which compound leaves arise. Above the ground, each compound leaf consists of 4 to 8 pairs of oblong–elliptic, glabrous, coriaceous, slightly succulent leaflets borne on an elongate rachis with a succulent petiole (Mayo *et al.*, 1997). The petiolule of the leaflet is very short and attached to the central rachis.

The plant is commonly known as "Zanzibar Gem" "Fat Boy" "ZZ Plant", "Eternity Plant" or "Golden tree". This indoor foliage plant is 'unique' in its exquisite appearance. It has no apparent limiting insect or disease problems under interior conditions and is extremely tolerant to low light and drought (Chen *et al*., 2002). The ability of the plant to withstand water stress and low light has elevated its horticultural importance at international level. (Chen and Henny, 2003). Since its introduction in the Dutch nurseries during the year 1996 (Horwood, 2007), it has emerged as an important ornamental plant for 'interiorscaping' (Papafotiou and Martini, 2009). *Z. zamiifolia*, is gaining popularity as an indoor plant in India too, for its elite characteristics and performance under reduced light and restricted water.

ZZ plants are propagated vegetatively by leaf cuttings using leaflets (Chen and Henny, 2003). As ZZ plant is slow growing even under favourable production conditions, their productivity is low when leaflets used as propagation material. The bottleneck in its large-scale production is its slow rate of growth and lower rate of multiplication making it very expensive. Methods to enhance rate of multiplication can augment its production and decrease the cost of production. Hence, the present study aimed at use of growth regulators for early tuberization of leaves for faster multiplication.

Material and Methods

Stock plants of *Z. zamiifolia* were maintained in the low cost polyhouse of 'D' Block, GKVK, University of Agricultural Sciences, Bengaluru -560065. Individual leaflets from third and fourth pair of matured leaflets from the base of the petiole were collected from healthy stock plants (Fig 1, & 1a). Cut end of the leaflets were dipped in rooting hormones viz; IAA, IBA and NAA at 1000 ppm, 2000ppm, 3000ppm, 4000ppm, and 5000ppm for 30 seconds and planted in the rooting medium Vermicompost and coirpith in combination in equal proportions (1:1 by volume) used as rooting medium. Totally, there were sixteen treatments, in each treatment, five leaflets were planted in a pot constituting to represent five replications. The pots were regularly watered once in a week till they attained field capacity during the experimental period of 90 days. The observations were recorded on size of rhizomes, number of roots, root length, and number of sprouts at 30th, 60^{th,} and 90th day of plating. The experiment was laid out in Completely Randomized Design and data was analysed using appropriate statistical tools.

Results and Discussion

The initiation and formation of rhizome follows a definite pathway in ZZ during vegetative propagation (Fig. 2). Rhizome initiation was noticed at the cut distal end of the leaflet. The white or creamy white inner tissue emerges out which gradually develops into rhizome. As the rhizome develops, roots emerge from the dorsal surface of the newly formed rhizome. Cutter (1962) also reports that the detached leaflets form a tuberous swelling, from where roots and one or more buds emerge, at the base of the leaflet stalk (petiolule).

Fig. 2. Tuber formation, root and shoot initiation from growth regulator treated leaflets of *Z. zamiifolia*

Similar regeneration occurs at the proximal end of any cut across midrib and in the absence of the mid rib, at the base of the main lateral veins. It is always associated with vascular tissue. These rhizomes are formed by the downward-movement of food material and its accumulation in the distal end. Engler (1881), reported that growth hormones may be involved in rhizome formation due to biologically active hormones present in the leaflet of *Z. zamiifolia*, with the complete formation of the rhizomes, adventitious shoot buds appear on the dorsal surface of the rhizome.

Plant growth regulators have been used to induce roots from stem cuttings in several ornamental plants. However, use of growth regulators for induction of rhizomes or rooting of leaves are limited. In the present study, among the three auxins tried, significantly higher rhizome diameter was recorded at 30th day in leaflets treated with NAA 1000ppm and diameter increased significantly as the days advanced at 60th and 90th day.

Number of roots observed differed significantly at 30th , 60th and 90th day and more roots were produced when treated with IAA 4000 ppm, IBA 4000 & 5000 ppm and NAA 4000 ppm at 30th day. However, at 60th and 90th days significantly more roots had formed when treated with IBA 5000 ppm and NAA 3000 ppm. Similarly, significant difference was also noticed in the length of roots at 30th, 60th and 90th days which was more in IAA 2000 ppm treated leaves at 30th day and IBA 5000 treated leaves at 60th, IBA 3000 at 90th days. Formation of plantlets was noticed at 90th day, only in NAA treated leaflets (Table 1).

Early tuberization and shoot initiation at 30th day and subsequent plantlet formation at 90th day with maximum number of plantlets (100% of leaflets developing into plantlets) was noticed in leaflets treated with 3000 ppm NAA. Further, NAA 5000 ppm resulted in maximum shoot length (11.42 cm). Among the growth regulators tested, NAA 3000 ppm has given better results in terms of time taken for initiation of tubers, tuberization and formation of new shoots.

Seneviratne *et al*. (2013) in their study reported basal leaflets *Z. zamiifolia* without rachis as best cutting for rapid propagation while Lopez *et al*. (2009) reported rapid propagation of *Z. zamiifolia* can be done by apical leaflet cuttings under relatively low light intensity. Single leaflets were also used in the present study after treating them with growth regulators. There are no earlier reports on use of growth regulators to enhance the production of plantlets in *Z. zamiifolia.* The present results proved that use of growth regulators contributed for the development of plants. This has a practical application in largescale production of plants.

Conclusion

The growth regulators employed for the induction of development of rhizome, root and shoot have influenced the plantlet formation at a faster rate. NAA 3000 ppm is very effective in inducing the developmental stages in accelerated manner and formation of plantlets at a shorter period.

Abstract

Limited information is available on trait relations of rye landraces in world and the objectives of this study were to understand the relationships among traits, and to document trait profile of some rye landraces. Effective interpretation of the data is important at all stages of plant improvement and the genotype by trait (GT) biplot was used for two-way wheat dataset as genotypes with multiple traits. For this propose, 18 rye genotypes with specific characteristics were evaluated in randomized block design with four replications. The GT biplot explained 61% of the total variation (the first two principal components explained 40 and 21%, respectively). The polygon view of GT presented for 11 different traits of rye landraces showed six vertex landraces as genotypes G1, G3, G6, G8, G11 and G13. The landrace G8 had the highest values for most of the measured traits. The genotypes G8 and G7 following to genotypes G3, G18 and G19 could be considered for the developing of desirable progenies in the selection strategy of rye improvement programs. The landraces used in this study were found to be useful sources for genetic variability for future breeding that targets to improve grain yield and other agronomic traits of rye.

Key words: genotype-by-trait, principal components, trait associations

Introduction

The insufficient knowledge of the interrelationship among various characters and the practice of unilateral selection for agronomic characters frequently results in retrograde or less than optimal results in plant breeding program. Correlations between different traits is an aspect which should be kept in mind for better planning of selection programs because they show relationships among independent characters and the degree of linear relation between these characters (Seibel and Weiper, 2001). Seed yield is a quantitative trait, which is largely influenced by the environment and the response to direct selection for seed yield may be unpredictable and breeders are interested to use good criteria for seed yield. Therefore, there is the need to examine the relationships among various traits, especially between seed yield and other agronomic traits. Genetic studies in winter cereals like wheat and triticale have established that traits like the number of plant per area, the number of seeds per spike and thousand seed weight are the major traits of yield potential and genetic gains through selection based on these components have been realized in practice (Zečević et al. 2004; Dogan and Senyigit, 2016). Bhutta (2006) has concluded that the number of seeds per spike, the number of plant per area and spike length correlate with seed yield per plant and according to Koutis et al. (2012) seed yield correlates with plant height, the number of plant per area and thousand seed weight.

According to Del-Blanco et al. (2001) some yield components such as the number of plant per area, the number of seeds per spike and thousand seed weight have significant contribution to seed yield. It has been reported that the number of plant per plant, plant height, thousand seed weight and spike length have significant correlation with seed yield (9). Effective interpretation of the data on breeding programs is important at all stages of plant improvement, particularly when it is only possible to select yield components. Several

methods have been used in exploration for an understanding of the data structure which may differ in overall appropriateness; different methods usually lead to the similar conclusions for a given dataset. Yan et al. (2000) have developed a genotype main effect (G) plus genotype by environment (GE) biplot methodology for the graphical analysis of multi-environment trial data. A biplot is a plot that simultaneously displays the effects of genotypes and the environment and the GGE refers to G main effect plus GE interaction effect. The GGE biplot can also be used for all types of two-way dataset such as genotypes with multiple traits. Yan and Rajcan (2002) have used a genotype by trait (GT) biplot, which is an application of the GGE biplot to study the genotype by trait data.

The present study was performed to study the interrelationship of rye yield components and their contribution to seed yield using GT biplot technique. The information so derived could be employed in reaching further breeding strategies and selection of methods to develop new high yielding rye genotypes.

Materials and methods

The experimental field design (Maragheh, Iran) was a randomized complete block design (RCBD) arrangement with four replications. The experiment included 18 rye genotypes, which represent a range of phenotypic variation in maturity, adaptation zone, yield potential and date of release. The small samples of experimental seed materials were obtained from Genebank Department of Leibniz Institute of Plant Genetics and Crop Plant Research (IPK) in Gatersleben, Germany. These samples were propagated in growing season 2014 and their name and origin are given. Tillage of all plots was performed prior to sowing date and fertility was constrained by low organic matter and phosphorus contents.

The fertilizer application was performed before sowing, 50 kg $ha^{-1}$of N, 25 kg ha^{-1} of P and 15 kg ha^{-1} of K were spread on the surface and tilled into the soil and the weeds were controlled chemically by MCPA (2-methyl-4-chlorophenoxyacetic acid). Plant density was 250–300 plants m^{-2}. Plant height (PH), spike length (SL), awn length (AL), seed number per spike (SNS), first internode weight (FIW), spike weight (SW), flag leaf length (FLL), and number of spike per area (NSA) were measured based on ten guarded plants, which were randomly selected from each plot. Also, thousand seed weight (TSW) and seed yield (SY) of each plot were measured and harvest index (HI) were computed based on ratio of SY to biological yield. The genotype × trait (GT) biplot was used to show the two-way pattern of rye genotypes' traits in a biplot. Because the traits were measured in different units, the biplots were generated using the standardized values of the trait means using GGE biplot software (Yan, 2001).

Results and discussion

The GT biplot explained 61% (40 and 21%, for the first two principal components, respectively) of the total variation of the standardized data and this relatively moderate percentage reflects the complexity of the relationships among the measured traits. The polygon view of the GT biplot helps identify genotypes with the highest values for one or more traits and provides the best way for visualizing the interaction patterns between genotypes and traits and to effectively interpret a biplot. For this purpose, the genotypes that are connected with straight lines so that a polygon is formed with all other traits contained within the polygon. The Fig. 1, as polygon view, presents data of 18 rye genotypes in eleven traits and the following information can be understood: the vertex genotypes in this investigation are G1, G3, G6, G8, G11 and G13. These genotypes are the best or the poorest genotypes in some or all of the traits since they had the longest distance from the origin of biplot. Therefore, genotype G8 had the highest values for seed number per spike (SNS), first internode weight (FIW), plant height (PH), spike weight (SW) and thousand seed weight

(TSW) traits while genotype G3 had the highest values for spike length (SL) and awn length (AL). Genotype G11 had the highest values for number of spike per area (NSA), seed yield (SY) and harvest index (HI) while genotype G3 had the highest values for flag leaf length (FLL). The vertex genotype and the other genotypes which fell in related sector had good amounts of the above mentioned traits. The other vertex cultivars (G1 and G13) and related sectors were not suitable performance for the measured traits (Fig. 1). Different vertex genotypes and their related genotypes which are located in different sections of biplot are good candidates for examination heterosis (Yan et al. 2007) for hybrid production in rye using these genotypes or pure lines. Also, genotype G11 could be used for improving seed yield in breeding program.

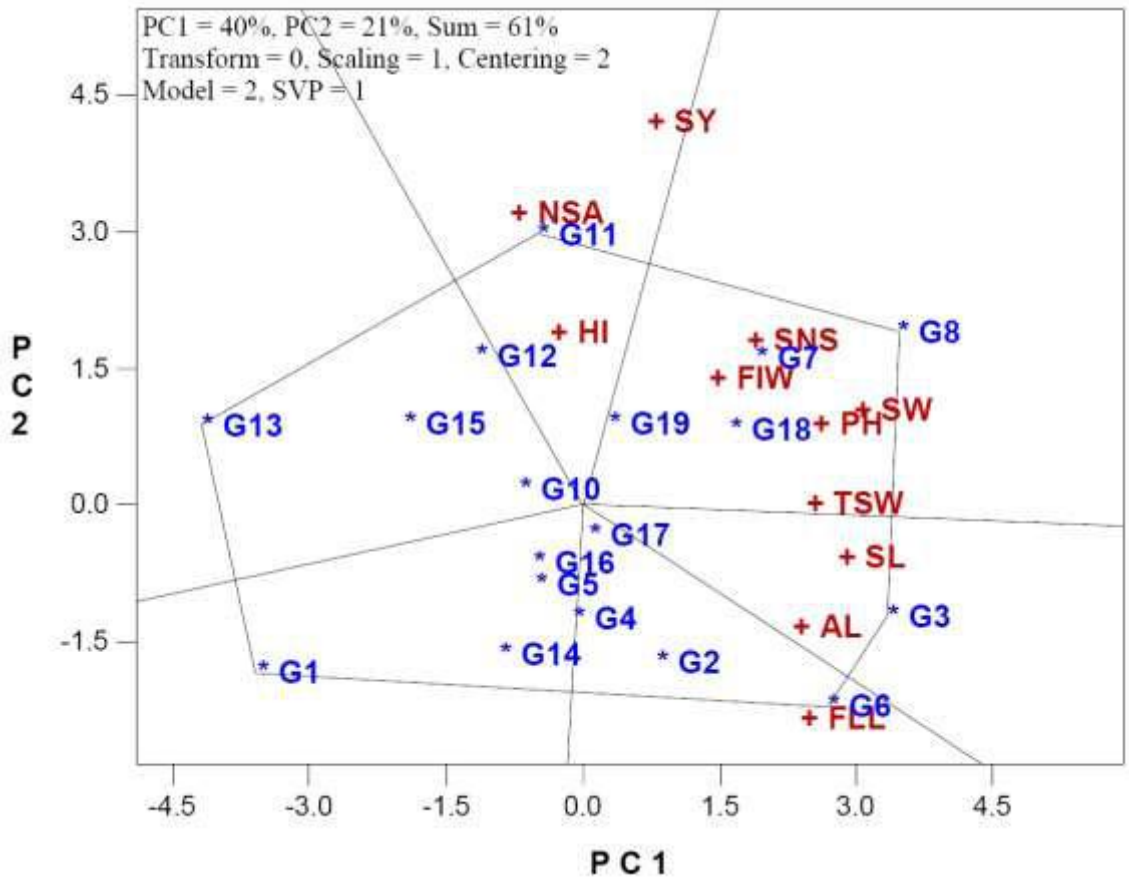

Fig. 1. Polygon view genotype by trait biplot, showing which genotype had the highest values for which traits for 18 different rye genotypes

Provided that the GT biplot model described relatively a sufficient amount of the total variation, the correlation coefficient between any two traits is approximated by the cosine of the angle between their vectors (Yan and Kang, 2003). The most prominent relations by vector-view biplot at the first year (Fig. 2) are: a strong positive association between SW and PH; between TSW and SL; between FIW and SNS; between AL and FLL; and between HI and NSA; as indicated by the small obtuse angles between their vectors. There was a near zero correlation between FLL with FIW and SNS, between SY with TSW and SL, and between PH and SW with NAS and HI (Fig. 2) as indicated by the near perpendicular vectors. There was a negative correlation between FLL with NAS and HI as indicated by the near an angle of approximately 180 degrees. Some above discrepancies of the biplot predictions and original data were expected because the biplot accounted for the total variation. Potential sources of genetic variation are important to allow rye breeders to deal with changing

environmental condition and large collections of genetic stocks do not exist for rye and this point is best illustrated by the fact that in the past decade a few high yielding cultivars have developed. While large collections of genetic stocks do not exist, there are some local landraces available to breeders but variation exists for most traits have not been investigated. The data obtained in this study could be useful for rye breeders in efforts to increase yield. The correlation coefficients between the seed yield and yield components showed good variation, and the results suggest that the seed number per spike, first internode weight, number of spike per area and harvest index are the primary selection criteria for higher seed yield in rye.

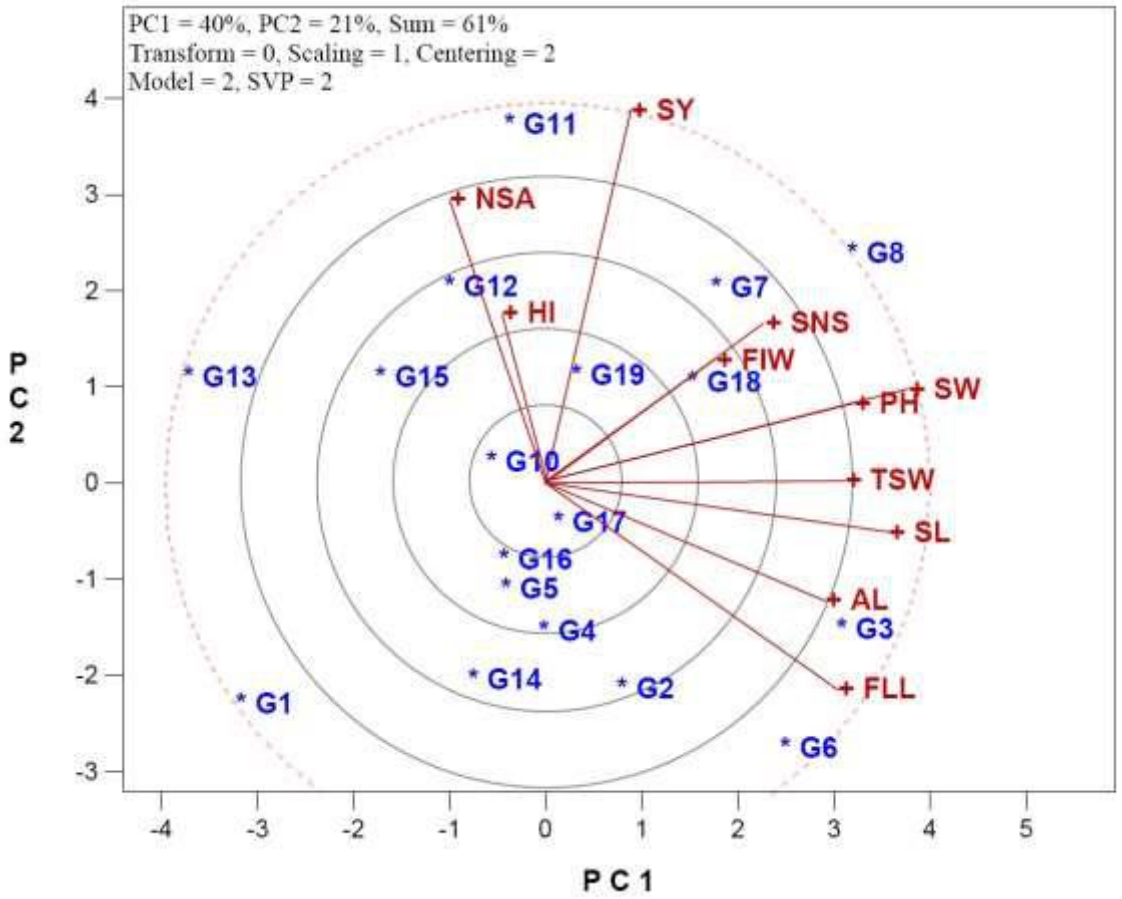

Fig. 2. Vector view genotype by trait biplot, showing the interrelationship among all measured traits for 18 different rye genotypes

The GT biplot method is an excellent tool for visual genotype by trait data analysis because it is a powerful tool and can be used to graphically address research questions (Yan, 2014). Compared with conventional methods, the GT biplot approach has some advantages: (i) graphical presentation of the data, which greatly enhances our ability to understand the patterns of the data, (ii) more interpretative and facilitates pair-wise genotype or trait comparisons and effectively reveals the interrelationships among the rye traits, (iii) it facilitates identification of possible which-won-where patterns or which-lost-where patterns, and (iv) it can be used in independent culling based on multiple traits and in comparing selection strategies. (Yan and Kang, 2003; Yan, 2014). In conclusion, based on the GT biplot, seed number per spike (SNS), first internode weight (FIW), number of spike per area (NSA), and harvest index (HI) were identified as traits suitable for selection for yield improvement in rye. Thus, selecting for these traits is expected to lead to improved yield and this suggests that selection index that incorporates these traits will not only result in the development of high

yielding cultivars but with other desirable agronomic traits. From my observations, it appears possible to improve exotic rye landraces by selecting for genotypes with higher values of the above mentioned traits. Also, almost half of studied genotypes including G3, G7, G6, G11, G17, G18 and G19 are good candidates for improving most of the measured traits due to existence of good genetic variability in this materials.

Conclusions

The biplot is a useful methods for visual genotype by trait data analysis and compared with conventional methods, the biplot has some advantages. The seed number per spike (SNS), first internode weight (FIW), number of spike per area (NSA), and harvest index (HI) were identified as traits suitable for selection for yield improvement in rye. Also, genotypes G3, G7, G6, G11, G17, G18 and G19 are good candidates for developing new cultivars.

Acknowledgments

We wish to thank kindly Professor Wei-Kai Yan (Eastern Cereal Oilseed Research Center of Agriculture and Agri-Food Canada) for making available a time-limited version of GGEbiplot as "testBiplotxlsx".

Abstract

Phenological traits, yield, and fruit characteristics of nine plum cultivars of early maturation time were studied in the region of Belgrade (Serbia) in the five-year period (2013-2017). The control cultivar for comparison was 'Čačanska Rana'. The average time of flowering of tested cultivars was in the first half of April, and the average duration of flowering varied from 7.4 to 10.4 days. The average time of maturation ranged from June, 22 ('Boranka') to July, 14 ('Minerva'). The average yield per tree was lowest in the control cultivar, 'Čačanska Rana' (8.4 kg) and highest in the cultivar 'Dalikatnaya' (25.5 kg). Compared to control, significantly higher yield was achieved in four cultivars: 'Dalikatnaya', 'Opal', 'Minerva', and 'Katinka'. The lowest vigor was recorded in the cultivar 'Katinka', and the highest in the cultivar 'Opal'. The average fruit weight ranged from 22.9 g in the cultivar 'Katinka' to 55.9 g in the cultivar 'Čačanska Rana'. Compared to control, fruit weight was significantly lower in all cultivars except 'California Blue'. Soluble solids content was lowest in the cultivar 'Boranka' and highest in cultivars 'Opal', 'Herman' and 'Minerva'. The best rated cultivars for fruit appearance were 'Čačanska Rana' and 'California Blue', while cultivars 'Opal' and 'Katinka' had the best scores for taste.

Key words: *Prunus domestica, flowering, maturation, yield, fruit characteristics*

Introduction

Plum (*Prunus domestica* L.) is the most important fruit species in Serbia. The average annual production of 403.060 t in the period of 2014-2016 ranks Serbia on the third place in the world, after China and Romania (FAOSTAT, 2018). The assortment of plum cultivars is dominated by those intended for processing. The most of produced plum fruits is processed into brandy (more than 70%), while much smaller amounts are dried, frozen, and processed into other products. Fresh consumption of plums is quite small. The highest profit in plum production is gained by growing table cultivars, especially that of early maturing time.The most important cultivars for fresh consumption are 'Čačanska Lepotica' and 'Čačanska Rana'. In recent years, there is a tendency to increase export of fresh fruits, mostly to Russia (Milatović, 2013). A lot of work has been done in the world on creation of new European plum cultivars with improved characteristics, such as better adaptation to different environmental conditions, increased disease resistance, self-fertility, higher yield and better fruit quality. In the last 20 years more than 170 new plum cultivars were released in Europe (Butac et al., 2013). The introduction of new foreign cultivars and their study in Serbian climatic and soil conditions allow better choice of cultivars, and may improve the production of plums. The aim of this study was to evaluate phenological traits, yield and fruit characteristics of European plum cultivars of early maturation time. The best performing cultivars will be recommended for growing in the region of Belgrade, as well as in other regions with similar environmental conditions.

Material and Methods

The study was conducted in the plum collection orchard at the Experimental Station "Radmilovac" of the Faculty of Agriculture in Belgrade during the period of five years (2013–2017). The orchard was planted in 2009. The rootstock is Myrobalan (*Prunus cerasifera* Ehrh.) seedling, training system is central leader, and planting distance is 4.5 m × 3 m. The study included eight plum cultivars: 'Boranka' (from Serbia), 'Dalikatnaya' (Belarus), 'Herman' (Sweden), 'California Blue' (USA), 'Katinka' (Germany), 'Minerva' (Romania), 'Opal' (Sweden) and 'Ruth Gerstetter' (Germany). Control cultivar for comparison was 'Čačanska Rana'. All cultivars are represented by five trees.

Flowering was recorded according to recommendations of the International Working Group for pollination: start of flowering – 10% open flowers, full bloom – 80% open flowers, end of flowering – 90% of the petal fall (Wertheim, 1996). Trunk cross-sectional area (TCSA) was calculated on the basis of trunk circumference measured at the height of 30 cm above the ground level. Cumulative yield efficiency was calculated by dividing the cumulative yield over five years by TCSA in the last year (2017). Fruit characteristics were measured on a sample of 25 fruits per cultivar. Fruit shape index was calculated using the formula: length × length / width × thickness. Soluble solids were determined by refractometer and total acids (expressed as malic acid) by titration with 0.1 N NaOH. Sensory characteristics of the fruit (appearance and taste) were evaluated by a five-member jury, scoring the cultivars using the scale from 1 to 5 points.

The obtained data were statistically analyzed using analysis of variance. The significance of differences between mean values was determined using Duncan's multiple range test at 0.05 level of probability.

Results and Discussion

Average time of flowering of tested cultivars was in the first half of April (Table 1). The earliest start of flowering was recorded in the cultivar 'Dalikatnaya' (March, 30), and the latest in cultivars 'Herman' and 'California Blue' (April, 4). The average difference between cultivars with earliest and latest flowering was six days.

Table 1. Phenological characteristics of plum cultivars (average, 2013–2017).

Cultivar	Flowering dates			Duration of flowering (days)	Abundance of flowering (0-5 scale)	Harvest date
	Start	Full	End			
Čačanska Rana (control)	1 April	4 April	11 April	9.8	3.9	3 July
Boranka	2 April	5 April	11 April	8.8	4.2	22 June
Dalikatnaya	30 March	2 April	9 April	10.4	4.2	13 July
Herman	4 April	6 April	11 April	7.4	4.0	30 June
California Blue	4 April	6 April	11 April	7.6	3.9	5 July
Katinka	2 April	5 April	10 April	8.0	3.7	5 July
Minerva	2 April	5 April	11 April	8.2	3.6	14 July
Opal	2 April	5 April	11 April	9.0	2.7	10 July
Ruth Gerstetter	2 April	5 April	11 April	8.4	4.5	25 June

Among years, the earliest flowering was in 2014, when the average date of the flowering onset for all cultivars was March, 24. The latest flowering was in 2013 when the average date of the flowering onset was April, 17. The difference between years with earliest and latest flowering was 24 days and it was much bigger than the difference between cultivars.

The average duration of flowering ranged from 7.4 days ('Herman') to 10.4 days ('Dalikatnaya'). Among years, the average duration of flowering for all cultivars ranged from

6.8 days in 2015 to 10.6 days in 2016. The most abundant flowering was recorded in cultivar 'Ruth Gerstetter' (score 4.5 on the 0-5 scale). The lowest flowering intensity (score 2.7) was recorded in the cultivar 'Opal'.

The range of fruit maturity was from June 22 ('Boranka') to July 14 ('Minerva'). For most cultivars the earliest fruit maturation was in 2016, and the latest in 2013 or 2014. Difference between years with earliest and latest fruit maturation varied from 4 to 8 days.

Both flowering and fruit maturation of plum cultivars in the region of Belgrade were earlier comparing to Czech Republic (Blažek et al., 2004), Central Bulgaria (Dragoyski et al., 2010), Northern Montenegro (Božović and Jaćimović, 2012) and Poland (Markuszewski and Kopytowski, 2013). These differences can be explained by different environmental conditions between the study regions.

The average yield per tree was lowest in the control cultivar 'Čačanska Rana' (8.4 kg) and highest in the cultivar 'Dalikatnaya' (25.5 kg) (Table 2). Compared to control, significantly higher yield was achieved in four cultivars: 'Dalikatnaya', 'Opal', 'Minerva', and 'Katinka'.

Table 2. Yield, trunk cross-sectional area (TCSA), and cumulative yield efficiency (CYE) of plum cultivars.

Cultivar	Yield (kg per tree)						TCSA	CYE
	2013	2014	2015	2016	2017	Average	(cm^2)	(kg/cm^2)
Čačanska Rana (control)	2.8	12.1	9.8	7.4	9.9	8.4 d	156.5 ab	0.27
Boranka	3.9	7.7	11.9	4.4	19.6	9.5 cd	137.1 bc	0.35
Dalikatnaya	8.7	51.4	14.4	47.4	5.6	25.5 a	163.9 ab	0.78
Herman	4.8	21.3	21.9	11.2	1.6	12.2 bcd	121.1 bc	0.50
California Blue	5.3	14.7	19.3	13.2	21.7	14.8 bcd	119.6 bc	0.62
Katinka	5.9	34.7	4.5	28.1	7.3	16.1 bc	101.5 c	0.79
Minerva	9.7	31.3	9.0	29.8	5.4	17.0 b	131.7 bc	0.65
Opal	8.9	45.5	7.5	26.9	6.2	19.0 ab	186.5 a	0.51
Ruth Gerstetter	2.7	17.2	15.1	3.5	5.3	8.8 d	166.6 ab	0.26

Mean values followed by the same letter within a column do not differ significantly according to Duncan's multiple range test at $P \leq 0.05$.

Among studied cultivars, the lowest vigor was found in the cultivar 'Katinka', and the highest in the cultivar 'Opal'. Our results of low vigor and high yield of cultivar 'Katinka' confirm previous findings of Blažek and Pišteková (2009).

Cumulative yield efficiency ranged from 0.26 to 0.79 kg/cm^2. Cultivars 'Katinka' and 'Dalikatnaya' stands out for high cumulative yield efficiency. On the other side, cultivars 'Ruth Gerstetter', 'Čačanska Rana' and 'Boranka' are characterized by low yield efficiency.

Fruit weight ranged from 22.9 g in the cultivar 'Katinka' to 55.9 g in the cultivar 'Čačanska Rana' (Table 3). Compared to control, fruit weight was significantly lower in all cultivars except 'California Blue'.

Stone weight ranged from 1.12 g ('Herman') to 2.80 g ('Čačanska Rana'), and its share in the fruit weight ranged from 3.0% ('California Blue') to 5.2% ('Katinka'). Significant differences were found between cultivars for fruit dimensions. Fruit length was highest in the control cultivar ('Čačanska Rana'), whereas width and thickness were highest in the cultivar 'California Blue'. Based on the fruit dimensions the shape index was calculated, whose values ranged from 1.03 in 'California Blue' (round shape) to 1.83 in 'Čačanska Rana' (elliptic shape). Stalk length was shortest in 'Herman' (0.8 cm), and longest in the control cultivar, 'Čačanska Rana' (2.1 cm).

Results of fruit characteristics are in accordance with the previous findings for some cultivars (Hodun et al., 1998; Blažek et al., 2004; Ogašanović et al, 2007; Milatović et al., 2011; Milošević and Milošević, 2011; Glišić et al., 2015).

Table 3. Fruit characteristics of plum cultivars (average, 2013–2017).

Cultivar	Fruit weight (g)	Stone weight (g)	Stone share (%)	Fruit dimensions (cm)			Shape index	Stalk length (cm)
				Length	Width	Thickness		
Čačanska Rana (control)	55.9 a	2.80 a	5.0	5.2 a	4.2 a	3.6 bc	1.83	2.1 a
Boranka	34.8 c	1.38 cd	4.0	3.9 cd	3.7 bc	3.7 bc	1.08	0.9 fg
Dalikatnaya	45.3 b	2.28 b	5.0	4.2 bc	4.0 ab	4.0 ab	1.07	1.8 b
Herman	30.0 cd	1.12 d	3.7	3.6 d	3.3 de	3.3 cd	1.15	0.8 g
California Blue	52.4 ab	1.60 c	3.0	4.3 b	4.3 a	4.3 a	1.03	1.5 ed
Katinka	22.9 d	1.18 d	5.2	3.8 cd	3.1 e	3.1 d	1.53	1.3 de
Minerva	33.9 c	1.29 cd	3.8	4.2 bc	3.5 cde	3.6 bc	1.42	1.1 ef
Opal	31.7 c	1.33 cd	4.2	3.8 cd	3.6 cd	3.5 cd	1.15	1.6 bc
Ruth Gerstetter	29.1 cd	1.14 d	3.9	3.7 d	3.5 cde	3.4 cd	1.15	1.0 efg

Mean values followed by the same letter within a column do not differ significantly according to Duncan's multiple range test at P≤0.05.

Cultivars 'Opal', 'Herman' and 'Minerva' are characterized by high soluble solids content (15.6-16.0%). On the other hand, lowest soluble solids content (12.8%), significantly lower than in previous cultivars, was found in the earliest maturing cultivar - 'Boranka' (Table 4). Cultivar 'Dalikatnaya' is characterized by high total acids content (1.94%), that was significantly higher than in all other cultivars.

Table 4. Indicators of fruit quality of plum cultivars (average, 2013–2017).

Cultivar	Soluble solids (%)	Total acids (%)	Soluble solids /Total acids	Sensory evaluation (1-5 scale)	
				Appearance	Taste
Čačanska Rana (control)	13.8 ab	1.13 b	12.2	4.6 a	3.7 ab
Boranka	12.8 b	1.06 bc	12.1	3.2 c	3.1 b
Dalikatnaya	15.2 ab	1.94 a	7.8	3.7 bc	3.6 ab
Herman	15.8 a	0.88 bc	17.9	3.7 bc	3.6 ab
California Blue	14.7 ab	1.14 b	12.9	4.2 ab	3.4 b
Katinka	14.8 ab	0.84 c	17.6	3.6 c	4.1 a
Minerva	15.6 a	0.95 bc	16.4	3.5 c	3.3 b
Opal	16.0 a	1.09 bc	14.7	3.3 c	4.2 a
Ruth Gerstetter	14.6 ab	1.02 bc	14.3	3.8 bc	3.6 b

Mean values followed by the same letter within a column do not differ significantly according to Duncan's multiple range test at *P≤0.05*.

The ratio between contents of soluble solids and total acids (SSC/TA), rather than the very content of soluble solids, represents a reliable indicator of a cultivar's suitability for acceptance by consumers (Crisosto et al., 2004). Cultivars 'Herman' and 'Katinka' are characterized by high SSC/TA ratio (17.6-17.9).

The data on the chemical composition of fruits are in good agreement with most of the previous findings (Bohačenko et al., 2010; Milatović et al., 2011; Glišić et al., 2015).

The best rated cultivars for fruit appearance were 'Čačanska Rana' and 'California Blue', while cultivars 'Opal' and 'Katinka' were best scored for taste. Our results of good taste for cultivar 'Katinka' are in accordance with those of Hartmann (1998) and for cultivar 'Opal' with those of Kemp and Wustenberghs (1998).

Conclusion

Control cultivar, 'Čačanska Rana' is characterized by the best fruit appearance, especially by large fruit size. All other cultivars had significantly smaller fruit size, except 'California Blue'. However, productivity of 'Čačanska Rana' cultivar is low. Significantly higher yield was found in four cultivars: 'Dalikatnaya', 'Opal', 'Minerva', and 'Katinka'. Besides, cultivars 'Opal' and 'Katinka' had the best scores for taste.

MORPHOLOGICAL DIFFERENCES AMONG STRAINS OF OYSTER MUSHROOM GROWN ON DIFFERENT SUBSTRATES

Dušanka BUGARSKI*, Jelica GVOZDANOVIĆ-VARGA, Mirjana VASIĆ, Janko ČERVENSKI, Slobodan VLAJIĆ

Institute of Field and Vegetable Crops, Novi Sad, Republic of Serbia
*Corresponding author: dusanka.bugarski@ifvcns.ns.ac.rs

Abstract

Distribution of oyster mushroom production worldwide is based on its cultivation on available and low-priced substrates prepared using residues of cellulose materials from agricultural production. It is also based on its nutritive value and content of medically active matters that favourably affect the human organism, as well as the specific taste, which offers wide possibilities in cooking. Forms of oyster mushroom differ by colour, size and shape of the cap, length and width of stems, taste, as well as the physiological requirements during cultivation on different substrates in various climate conditions. Three isolated and determined strains of oyster mushroom (*Pleurotus ostreatus*) were studied - NS 77, NS 355 and NS 244. They were grown on residues of agricultural production most frequent on the territory of Vojvodina, such as wheat and soybean stems, and stalks of maize and sunflower, as individual substrates and in combinations with wheat straw. Variability was recorded among strains in most important morphological traits. The study monitored the ratios of cap weight (CW) and stem weight (SW), cap length (CL), cap width (CWi), stem length (SL) and stem width (SWi), as well as the number of mushrooms per bunch (NM). The monitored morphological traits have been expressed differently most of the time, depending on the strain, while in some cases the substrate was the determining factor. The number of fruiting bodies in strain NS 244 therefore varied in range 4.2-5.5, depending on the substrate. Strain NS 77 ranged from 7.4 to 11.2, while strain NS 355 ranged from 8.6 to 10.7. However, the highest values of cap weight of all three strains were recorded on maize stalk substrate.

Key words: *oyster mushroom, morphological traits, different substrates.*

Introduction

Oyster mushroom is a cosmopolitan plant which grows on all continents. It has long been adapted to different growing environments (Chang and Miles, 2004), and it can be cultivated on any surface which contains residues of cellulose materials from agricultural production - cellulose, hemicellulose, and nitrogen (Diana et al. 2012). It appears in different forms, varied in colour, size, shape and taste. Material included in the substrates prepared for oyster mushroom cultivation depends on the growing area (Bugarski *et al*., 2012). Agricultural waste area, as it is physically more accessible and therefore more cost-effective, is usually the substrate chosen for mushroom cultivation. For the purpose of increased yields and quality, mushroom cultivation substrates have lately been enriched with different supplements. In Spain, Pardo-Giménez et al. (2015) enriched wheat straw with 5, 10 and 15% degreased pistachios. In China, Yang et al. (2013) added cotton seed hulls and bran to wheat straw and rice straw. Mushrooms grown on substrates with a proportional content of cotton seed hulls developed larger caps, with greater cap length and shorter stems. As the quantity of cotton seed hulls in the substrates decreased 40-30-20, cap diameter decreased proportionally, ranging from 9.4 cm, 8.8 cm, to 7.8 cm. Cap weight also decreased from 22.93 g, 19.19 g, to 17.77 g, while stem length increased from 2.6 cm, 1.9 cm, to 3.2 cm.

In Taiwan, Hoa et al. (2015) showed significant differences between the morphological parameters of different species of P. *ostreatus* and P. *cystidiosus* grown on various substrates

(combination of sawdust, sugarcane and corncob). The highest cap length in both mushrooms was obtained if they were grown on corncob 100%, and lowest on sawdust 100%. Besides the effect of the substrate, type of mushroom also has a significant role; the number of obtained fruiting bodies in P. *cystidiosus* therefore ranged from 2.32 on sawdust 100% to 1.85 on substrate formula 50% sawdust +50% sugarcane bagasse, while it ranged from 10.32 on sawdust 100%, to 7.93 on corncob 100% in P. *ostreatus*. Stem length and stem width of oyster mushroom P. *ostreatus* (35.28 -39.21 mm) were lower on all substrates compared to P. *cystidiosus* (46.06 -57.84 mm).

In India, Mondal et al. (2013) enriched rice straw with different quantities of banana leaves, and the number of obtained fruiting bodies varied from 8.5 on banana leaves to 37.25 on sawdust. Stem length of oyster mushrooms grown on substrate formula banana leaves + rice straw 1:1 (2.47 cm) was significantly reduced compared to those grown on sawdust (3.80 cm), while cap diameter was significantly smaller on substrates banana leaves + rice straw 1:3 (4.13 cm), banana leaves + rice straw 3:1 (3.70 cm), and banana leaves + rice straw 1:3 (3.11 cm) compared to sawdust (7.79 cm). Contrary to the above, cap thickness was lower on sawdust in 2. (0.49 cm), and larger on banana leaves + rice straw mixture 3:1 (0.66 cm) and rice straw (0.64 cm).

Kitamoto et al (1995) explained the emergence of more fruiting bodies on some substrates by the higher content of carbohydrates (glucose, fructose and trehalose) in the substrate, while Shah et al. (2004) explained variations in cap weight by the relatively better availability of nitrogen, carbon and minerals from the substrates.

In Vojvodina, wheat straw is mainly used as the substrate for oyster mushroom growing. Wheat straw can be baled automatically after combining and thus made accessible for removal from the growing plots and transport. Since it is used in livestock breeding, it can be obtained throughout the year, so planning its purchase in advance is not necessary. Although soybean straw, corn stalks and sunflower stalks have to be collected and stored, previous studies have shown that they are better substrates than pure wheat straw. We have therefore focused our further studies on examining their effect on mushroom quality.

Material and Methods

Determination of morphological traits of oyster mushroom (*Pleurotus ostreatus*), produced in different substrates during three-year long studies, was conducted under the auspices of Institute of Field and Vegetable Crops Novi Sad, using the strains of *Pleurotus ostreatus* NS 77, *Pleurotus ostreatus* NS 355 and *Pleurotus ostreatus* NS 244 maintained in the collection of the Vegetable Crops Department (Bugarski, *et al*., 2012).

The substrates were prepared individually or with wheat straw (the substrate most often used in oyster mushroom cultivation in Serbia), in the following combinations: 1. wheat straw (S1), 2. wheat straw 50% + soybean straw 50% (S2), 3. wheat straw 50% + corn stalks 50% (S3), 4. wheat straw 50% + sunflower stalks 50% (S4), 5. soybean straw (S5), 6. corn stalks (S6), and 7. sunflower stalks (S7).

In order to obtain morphological traits of strains from each individual sample, three first bunches were taken and total fruiting bodies were counted and weighed individually. Cap weight and stem weight was measured, and cap-stalk ratio was determined. Cap diameters were measured using nonius (vernier) lines from stem root to tip and cross the widest part of the stem, at an angle of 90° to the previous diameter. Stem diameter was measured in the central part, while stem length was measured from the root, along the cap to the point of separation from the substrate.

For the analysis of morphological traits of P. *ostreatus*, principal components (PCA) were visualized so as to reduce the multi-dimensional nature of experimental data. Principal components are orthogonal and synthetic variables obtained as a linear combination of the

optimally-weighted observed variables, whose significance is defined by the regression coefficient (or weight) for observed variable as used in creating a principal component. The total number of components equals the total number of original variables. Since most of the obtained principal components are weighted with non-systematic components or noise to graphically display the results of PCA method, the first two artificial components are used to compute the scores on the principal component. Interpretation of a graphical display of data follows the geometry of a biplot (Kroonenberg, 1995).
Analysis and visualization of data was carried out in the R environment for statistical computing (R Core Team, 2015).

Results and Discussion

In strain NS 77, cap weight (CW) was uniform across all substrates, ranging from 10.08 to 11.24 g (Table 1.), while strain NS 355 on substrate Corn (S6) weighed 17.96 g, which was significantly higher than cap weight (CW) 14.90 g found on substrate wheat+soybean (S2). In strain NS 244, cap weight (CW) 26.17 g on substrate Corn (S6) was significantly higher compared to other substrates. Cap weight (CW) variations across substrates were the highest in strain NS 244 21.32%, compared to strain NS 355 17.03%, and strain NS 77 weighing only 10.32%. Cap weight (CW) was lowest in strain NS 77, and highest in strain NS 244, i.e. double the weight of strain NS 77.
Cap weight (CW) in all three NS strains was significnatly greater than cap weight obtained by Mondal et al. (2010) for oyster mushrooms grown on six different substrates, ranging from 1.77 g on sawdust to 6.41 g on rice straw, and equal to cap weight obtained by Yang et al., (2013) in their analysis of oyster mushroom growth on nine substrates (16.66-25.13 g).

Table 1. Cap weight (CW) and stem weight (SW) in NS strains of P. *ostreatus*

Substrate	Cap weight (CW) (g)			Stem weight (SW) (g)		
	NS 77	NS 355	NS 244	NS 77	NS 355	NS 244
Wheat (S1)	10.82a	15.38ab	21.44ab	3.53ab	4.80ab	5.43ab
Wheat+ soybean (S2)	11.24a	14.90a	21.65a	4.47ab	4.47a	6.24a
Wheat +corn (S3)	11.02a	16.18ab	20.75a	3.33b	5.35ab	6.44a
Wheat +sunflower (S4)	10.29a	16.61ab	20.83ab	4.19ab	4.71ab	3.67c
Soybean (S5)	10.76a	15.74ab	25.16bc	4.52a	4.37a	5.86a
Corn (S6)	11.13a	17.96b	26.17c	3.79ab	5.80b	5.79a
Sunflower (S7)	10.08a	16.58ab	20.59a	3.85ab	5.46ab	4.00cd

Note: a, b, c, d, - Means followed by the same letters within the columns are not significant (Tukey's multiple comparison test)

Stem weight (SW) in strain NS 77 on the substrate soybean (S5) was significantly greater than stem weight on the substrate wheat+corn (S3) (Table 1). Stem weight (SW) of strain NS 355 on substrate Corn (S6) was significantly greater than stem weight on the substrate soybean (S5) and wheat+soybean (S2), while significantly lower in strain NS 244 on wheat+sunflower (S4) and sunflower (S7), compared to other substrates. Stem weight variations according to substrates were the highest in strain NS 244 43.01%, compared to only 24.65% in strain NS 355, and 26.33% in strain NS 77. Stem weight (SW) was the lowest in strain NS 77, while the highest in strain NS 244.
Cap length (CL) (Table 2), in strain NS 77 was significantly lower on wheat+sunflower mixture (S4) compared to soybean (S5) and wheat (S1). In strain NS 355, it was significanly lower on wheat (S1) compared to wheat+corn (S3), whereas in strain NS 244 it was significantly higher on wheat+soybean (S2) compared to soybean (S5) and corn (S6). The

observed cap length (CL) variations, depending on the substrate, were the highest in strain NS 244 7.28%, compared to 7.12% in strain NS 355, and 6.27% in strain NS 77.
Depending on the substrate, cap width (CWi) (Table 2.) in strains NS 77 and NS 244 was uniform, but significantly lower in strain NS 355 on substrate soybean (S5) compared wheat+corn (S3). Cap width (CWi) variations were insignificant across substrates; the highest CWi was observed in strains NS 355, NS 244, and NS 77: 7.79%, 5.45%, and 4.07%, respectively.
Cap length (CL) and cap width (CWi) determined the shape of the cap, which was uniform across all the substrates, but varied depending on the strain; the cap of strain NS 355, especially strain NS 77 was almost round shaped, but an elongated cap was observed in strain NS 244 .

Table 2. Cap length (CL) and cap width (CWi) in NS strains of P. *ostreatus*

	Cap length (CL) (mm)			Cap width (CWi) (mm)		
Substrate	NS 77	NS 355	NS 244	NS 77	NS 355	NS 244
Wheat (S1)	65.83a	77.03a	93.01ab	59.85a	70.05ab	70.15a
Wheat+ soybean (S2)	64.99ab	78.01ab	99.05b	58.95a	69.56ab	73.35a
Wheat +corn (S3)	62.55ab	83.79b	97.33ab	60.41a	74.03b	74.29a
Wheat +sunflower (S4)	61.70b	78.75ab	97.26ab	59.05a	71.27ab	74.02a
Soybean (S5)	66.17a	79.46ab	91.93a	59.46a	68.26a	70.57a
Corn (S6)	65.25ab	79.98ab	91.84a	59.80a	71.25ab	70.82a
Sunflower (S7)	63.65ab	78.53ab	93.06ab	57.95a	69.69ab	71.05a

Note: a, b, - Means followed by the same letters within the columns are not significant (Tukey's multiple comparison test)

Mondal et al. (2010) obtained the results of cap diameters, ranging from 41.3 mm on banana leaves+rice straw (1:1) to 77.9 mm on sawdust, while Tupatkar & Jadhao (2006) obtained cap diameters of 28.38 cm^2 (equal to diameter of 60 mm) on wheat+soybean, 27.80 cm^2 on soybean straw, 27.05 cm^2 on corn stalk and leaves, and 24.50 cm2 on wheat straw, which is at the threshold of obtained NS values. Cap diameters of 63 mm on wheat straw 80%+wheat bran 20% and 104 mm on cotton seed hulls 80%+ wheat bran 20%, obtained by Yang et al. (2013), were the closest to CL and CWi values of NS strains.

Table 3. Stem length (SL) and stem width (SWi) in NS strains of P. *ostreatus*

Substrate	Stem length (SL) (mm)			Stem width (SWi) (mm)		
	NS 77	NS 355	NS 244	NS 77	NS 355	NS 244
Wheat (S1)	52.18a	38.72ab	30.76ab	11.34abc	12.23a	18.00a
Wheat+ soybean (S2)	54.32a	38.99ab	30.32ab	12.25ab	12.07a	21.55b
Wheat +corn (S3)	49.98a	41.88ab	34.82b	9.82c	12.73a	20.35ab
Wheat +sunflower (S4)	54.73a	37.98b	46.01c	13.95a	12.62a	46.99c
Soybean (S5)	54.53a	40.38ab	31.56ab	12.22ab	13.38a	20.54ab
Corn (S6)	56.38a	44.71a	33.52ab	10.59ac	12.68a	19.06ab
Sunflower (S7)	52.97a	40.28ab	27.91a	11.70abc	14.17a	18.40ab

Note: a, b, c, - Means followed by the same letters within the columns are not significant (Tukey's multiple comparison test)

Stem length (SL) (Table 3) in strain NS 77 was uniform on all substrates. It was significantly lower in strain NS 355 on wheat+sunflower (S4) compared to corn (S6), and significantly lower in strain NS 244 on sunflower (S7) compared to wheat+sunflower (S4), although higher in wheat+sunflower (S4) compared to other substrates. Stem length (SL) in strains NS 355

and NS 244 equaled the range of SL from 35.20 mm on substrate 50% sawdust+50% corn straw to 39.21mm on substrate 80% sawdust+20% sugarcane, as obtained by Hoa et al. (2015), while it was significantly higher in strain NS 77. Mondal et al. (2010) reported lower SL values than the values found in NS strains, ranging from 24.7 mm on banana leaves+rice straw mixture (1:1) to 38.0 mm on sawdust. Tupatkar & Jadhao (2006) obtained the SL values of 35.6 mm on wheat+soybean, 32.9 mm on soybean straw, 25.4 mm on corn stalk and leaves, and 22.6 mm on wheat straw. Jonathan et al. (2013) reported SL values within the range of 53-71 mm on sawdust, the closest to the SL value of strain NS 355.

Stem width (SWi) (Table 3) was uniform on all substrates for strain NS 355 (12.07-14.17 mm). Strain NS 77 had significantly lower SWi on wheat+corn mixture (S3) compared to wheat+sunflower (S4), wheat+soybean (S2) and soybean (S5), while significantly higher values were observed on wheat+sunflower mixture (S4) compared to wheat+corn (S3). The obtained SWi values were close to SWi of 8.52 mm on sawdust and 11.06 mm on corn straw, as reported by Hoa et al. (2015). The value of SWi in strain NS 244 was significantly lower on wheat (S1) compared to wheat+soybean (S2) and wheat+sunflower (S4), but significantly higher on wheat+sunflower (S4) compared to other substrates.

The highest SL with the variable SWi was obtained in strain NS 77, where SL was 5.3 times higher than SWi (56.38 x 10.59 mm) on substrate corn (S6), and 3.9 times higher than SWi (54.73 x 13.95 mm) on wheat+sunflower (S4) (Table 3). The lowest SL and highest SWi were observed in strain NS 244, often giving away the impression that the cap is attached to the substrate. On wheat+sunflower mixture (S4), SL was lower than SW (46.01 mm x 46.99 mm), while the stem was uniform in strain NS 355 where SL/SWi ratio ranged from 2.84 (40.28 mm x 14.17 mm) on sunflower (S7) to 3.61 (44.71 mm x 12.68 mm) on corn (S6).

Table 4. The number of fruiting bodies (NM) in NS strains of P. *ostreatus*

Substrate	NS 77	NS 355	NS 244
Wheat (S1)	7.44a	8.96ab	4.93a
Wheat+soybean (S2)	9.44ab	10.67a	4.22a
Wheat+corn (S3)	8.19ab	8.63b	4.70a
Wheat+sunflower (S4)	11.22b	10.56a	5.52a
Soybean (S5)	10.74ab	10.59a	5.04a
Corn (S6)	10.48ab	9.93ab	5.22a
Sunflower (S7)	10.52ab	9.04ab	5.52a

Note: a, b, - Means followed by the same letters within the columns are not significant (Tukey's multiple comparison test)

The number of fruiting bodies was uniform in strain NS 244 (4.22-5.52) (Table 4). In strain NS 77, it was significantly lower on substrate wheat (S1) compared to wheat+sunflower (S4), and significantly lower on wheat+corn mixture (S3) in strain NS 355 compared to wheat+sunflower (S4), wheat+soybean (S2), and soybean (S5). Kitamoto et al. (1995) explained the variation of fruiting bodies on certain substrates by the higher content of glucose, fructose and trehalose in the substrates.

The biplot revealed 72.9% of sample variability in the first dimension, and 14.8% in the second dimension (Fig. 1.). The first dimension separated the substrates which established morphological traits of strain NS 244, from the substrates defining morphological traits of strain NS 77, whereas substrates establishing morphological traits in strain NS 355, as the strain with the lowest variability, were displayed along the first axis located in the coordinate origin of the biplot. Strain NS 244 connected to stem width (SWi) was isolated in the second dimension, while other strains along the axis were located in the coordinate origin of the biplot as the substrates and strains with the lowest variation coefficient.

Cap weight (CW), stem weight (SW), cap length (CL) and cap width (CWi), as well as stem width (SWi) were positively correlated variables, with high values observed in strain NS 244. High values for the mushroom number (NM) were observed in strains NS 77 and NS 355. Positively correlated group of traits - cap weight (CW), stem weight (SW), cap length (CL), cap width (CWi), and stem width (SWi) - were negatively correlated with stem length (SL) and mushroom number (NM).

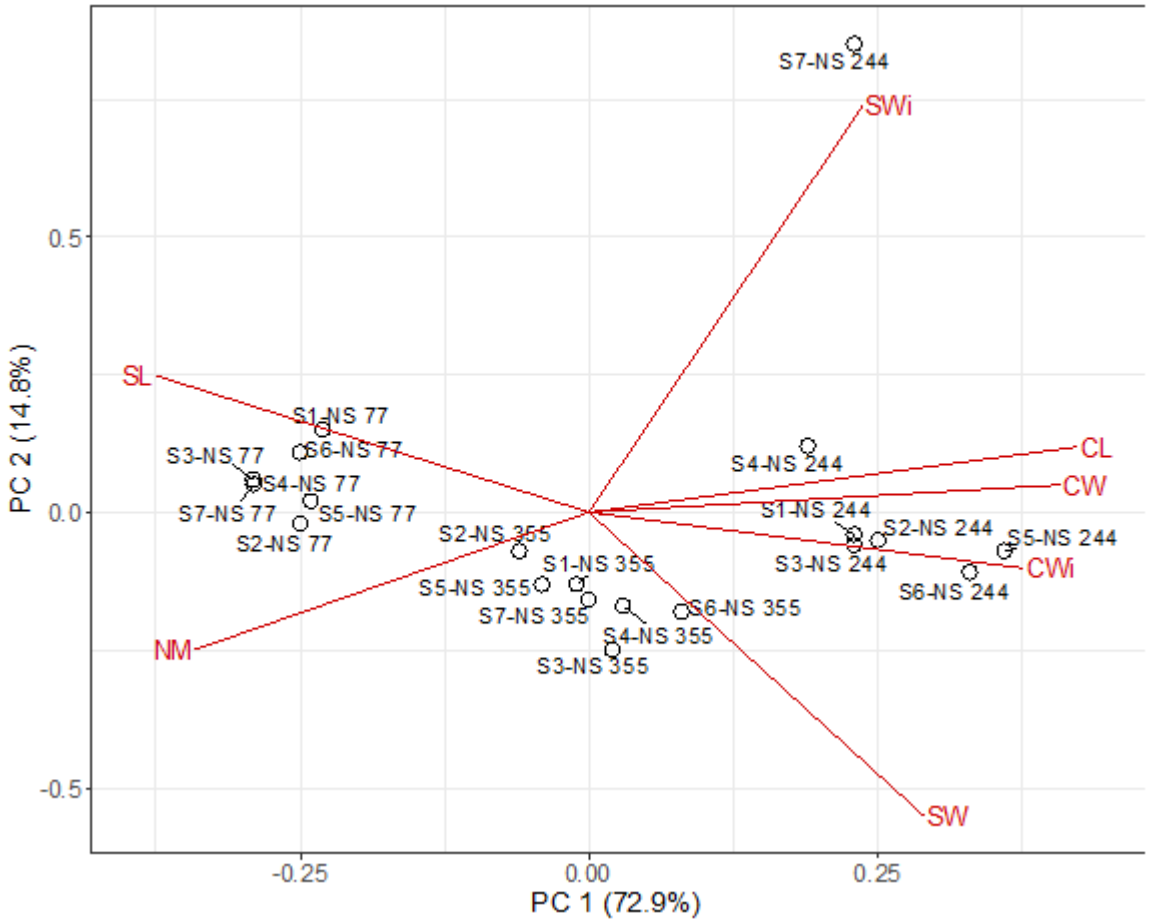

Fig. 1. Biplot display of morphological traits of NS strains of P. *ostreatus*

Conclusions

Comparison of morphological traits of the caps (cap weight CW, cap length CL and cap width CWi) revealed high variability between strains P. *ostreatus* (cap weight CW was doubled in strain NS 244 compared to strain NS 77); across substrates they were strain-specific and not significant.

The obtained results of stem weight (SW) and stem length (SL) revealed high variability between strains (NS 77> NS 355 > NS 244) as well as the results of stem width (SWi) (NS 244> NS 355 > NS 77), depending on the substrate. Soybean substrate (S5) had the highest effect on stem length (SL) in all three strains (NS 77, NS 355, and NS 244); a significant effect of substrate wheat+soybean (S2) was observed in strains NS 77 and NS 244; wheat+corn mixture (S3) significantly affected strains NS 355 and NS 244.

The number of fruiting bodies was uniform in strain NS 244, depending on the substrate, while strains NS 77 and NS 355 were significantly higher in wheat+sunflower (S4).

The biplot indicated a positive correlation between the morphological traits of stems - stem width (SWi) and stem weight (SW), a positive correlation between cap morphological traits - cap length (CL), cap width (CWi) and cap weight (CW), but a negative correlation with stem

length (SL) and the number of fruiting bodies in a bunch (NM). Depending on the composition of the tested substrates, high values of trait correlations - stem length (SL) and cap width (CWi) - were found on corn (S6); the highest values of cap width (CWi) and stem width (SWi) were observed on wheat+corn mixture (S3) as a group of positive variables, while the number of fruiting bodies (NM) had high values on sunflower stem substrates (S4 and S7).

PREDICTION OF SOIL MOISTURE IN DOUBLE CROPPING USING THE FAO AQUACROP MODEL

Abstract

Double cropping in the growing conditions in Serbia can be successful only with irrigation. For the establishment of an adequate irrigation schedule and water dosage it is necessary to monitor soil moisture in the rhizosphere layer. Soil moisture assessment instruments are not yet in mass use by irrigation system users. Prediction of soil moisture can also be performed by crop models. The aim of this paper is to test the reliability of soil moisture simulation in double cropping obtained by use of FAO Aquacrop model. The testing was carried out on the basis of the results of experimental research carried out on the chernozem type of the soil on a loessial terrace in Zemun Polje (Serbia). The soil moisture content in the rhizosphere horizon was measured in two fields. One field was double cropped with soybeans following wheat, and the other with green beans following wheat. The fields were irrigated by the sprinkling method. The soil moisture measurements in the experimental field were performed by a gravimetric method. Soil samples were taken at different depths, in three repetitions, at 10cm intervals up to a depth of 60cm, and then at every 20cm up to a depth of 1m. The reliability of simulations obtained using the Aquacrop model was rated by use of statistical parameters: root mean square error (RMSE), normalized root-mean-square error (nRMSE), the Willmott index of agreement (d) and the correlation coefficient (R). Simulation of soil moisture at the rhizosphere horizon shows good concurrence with measured values (RMSE<2.0, nRMSE<8.31, d>0.82, R>0.82). The one year results are showing that the Aquacrop model is able to simulate chernozem moisture of root zone of succession plants (in irrigation condition) accurately. This finding should be confirmed by the results of the research during several more vegetation seasons.

Key words: *Aquacrop model, soil moisture, soybeans, green beans, double cropping*

Introduction

The double cropping or succession planting system of plant production is the basis for growing the plants in sustainable production. In the climate zone in which Serbia is situated, a double cropping system is not possible without the use of irrigation. Since the succession planting is usually done at the end of June or early in July, it is almost certain that the plants will be exposed to severe drought at the very beginning of their vegetative life, since agro-meteorological analyzes indicates that in our region July and August are the periods with the largest climate deficit of water (Matović et al., 2013) and with very high air temperatures (Ruml et al., 2017). With the application of irrigation a water regimen of the soil, which provides conditions for the normal functioning of the physiological processes of succession planting crops from sowing to ripening, can be established. To assess the impact of water deficit and irrigation scheduling crop-models with different approaches are used in order to simulate the production process.

In this paper, the FAO crop yield model AquaCrop (Steduto et al., 2012; Raes et al., 2012) which simulate crop biomass and yield in response to water and other abiotic factors was used. Previously conducted studies in which model reliability was tested in simulation of

yields of different crops (Araya et al., 2010; Stricevic et al., 2011; Hussein et al., 2011; Heng et al., 2009; Hsiao et al., 2009; Zinyengere et al., 2011) all have reported positive results.
In addition to the yield simulation and irrigation regimen, the FAO AquaCrop model simulates moisture in the soil, based on input data on soil characteristics, climate and plant cover. In contrast to the studies in which the AquaCrop model was used to simulate yield and biomass, a significantly smaller number of studies focused on simulation of moisture in the soil (Farahani et al., 2009; Katerji et al., 2013; Paredes et al., 2015; Mkhabela and Bullock, 2012).
The aim of this paper is to evaluate the justification of the use of the FAO AquaCrop model for moisture simulation in the rhizosphere layer of soil, based on data from a one-year experiment conducted on two irrigation fields (succession green beans and succession soybeans).

Material and Methods

The experimental field was located in Zemun Polje, on Chernozem soil on a loesial terrace. The land is characterized by favourable water-physical properties and is rich in humus. The texture composition of the surface horizon up to 50 cm of depth is clay loam, and from 50 cm to 200 cm there is the loam. Field water capacity was determined by the method of monolith, and the wilting point by Richards method. Values of field water capacity (FC) and wilting point (WP) are shown in Figure 1.

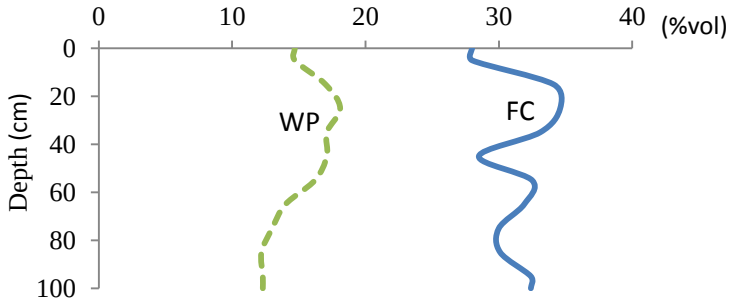

Figure 1. Field capacity (FC) and wilting point (WP) values on chernozem at experimental field in Zemun Polje.

The irrigation fields where the succession soybeans and succession green beans were grown are 0.76 ha. The test measurements were made on chosen basic plots. Those basic plots were square shaped, measuring 12 m by 1 2m. In the corners of the square, sprinklers of 10 m range have been installed. A uniform distribution of water deposits over the whole basic plot was achieved, which provided the same soil moisture conditions for all plants.
The soil moisture was controlled by a thermogravimetric method. Within a time span of about ten days, soil samples were taken at every 10 cm to a depth of up to 60 cm, and then every 20 cm to a depth of 1 m. The soil moisture control was carried out in three repetitions. The paper presents the average values of three measurements.
The sowing of succession crops was made on June 29th, a few days after wheat harvest. The harvest of green beans was on September 19th and the harvest of soybeans on October 30th. During the entire vegetation season records of the phases of growth and development of the plants were made (Table 1).

Table 1. Lasting of the phases of growth and development of the succession plants from the first day after sowing

Growth Stages	Soybeans		Green beans	
	Length (days)	Date	Lenght (days)	Date
From day 1 after sowing:		30-Jun		30-Jun
to emergence	6	06-Jul	6	06-Jul
to maximum canopy cover	54	23-Aug	34	03-Aug
to start of canopy senescence	98	06-Oct	69	07-Sep
to maturity	123	30-Oct	82	19-Sep

Soil humidity was simulated using the FAO AquaCrop crop model (http://www.fao.org/aquacrop). The model is user-friendly and requires a relatively small number of input parameters for climate, soil, agro-technical measures and plant characteristics. Climatic data from the Zemun Polje meteorological station provided the data necessary for the calculation of evapotranspiration by the Penman-Montheith method (minimal and maximal air temperature, relative humidity, insolation, wind speed). Data relates to 1987 when research was carried out. The amount of precipitation was measured on a daily basis, using a pluviometer located on the experimental field itself. Phenological phases of the development and development of the observed plant species were recorded on site (Tab.1). The stratigraphic and aqueous physical properties of the soil were determined in the described way (Figure 1). The missing data were taken from the crop model itself.

Soil moisture is simulated for the depth of the effective zone of the root system. In case of succession soybean the humidity is simulated for depth 0-80 cm, and for succession green beans 0-50 cm. These depths have been selected because they represent the depth of soil moistening by irrigation, which is the basis for calculating the amount of water needed for irrigation.

For the assessment of the reliability of soil humidity simulations, statistical parameters were used: root mean square error RMSE, normalized root-mean-square error nRMSE, Willmott index agreement d (Willmott et al., 1985) and correlation coefficient R.

Results and Discussion

According to the amount of precipitation, the vegetation season, in which the research was carried out, was approximate to the perennial average (Matović, 2000). The schedule of precipitation during the vegetation period is shown on Figure 2.

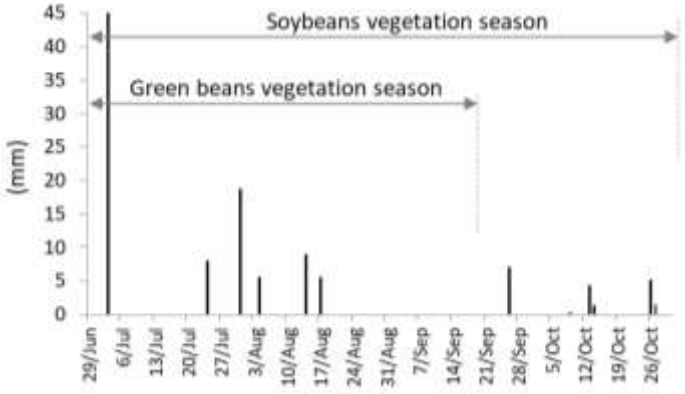

Figure 2. Precipitation schedule in the experimental field in Zemun Polje, starting from the date of sowing, until the harvest of succession soybeans and green beans

During its growing season, succession soybeans received 117 mm of rainfall and succession green beans 92 mm. Soybean was watered in 10 occasions, with a total quantity of 220 mm of

water, while green beans was watered, with a total of 197 mm of water also in 10 watering. That means that, excluding initial and final soil moisture, the soybeans had at its disposal a total of 337 mm of water, while green beans had 289 mm of water. Groundwater is deep (about 10 m depth), so it is considered that there is no ascendent touch of water from the underground.

The average values of chernozem humidity measured under the succession soybean (depth 0-0.8 m) and succession green beans (depth 0-0.5 m) are shown by dots in Figure 3. Simulation of soil moisture for the mentioned depths is represented by the curve line composed of daily values of soil moisture obtained by the water balance calculation (Raes et al., 2018).

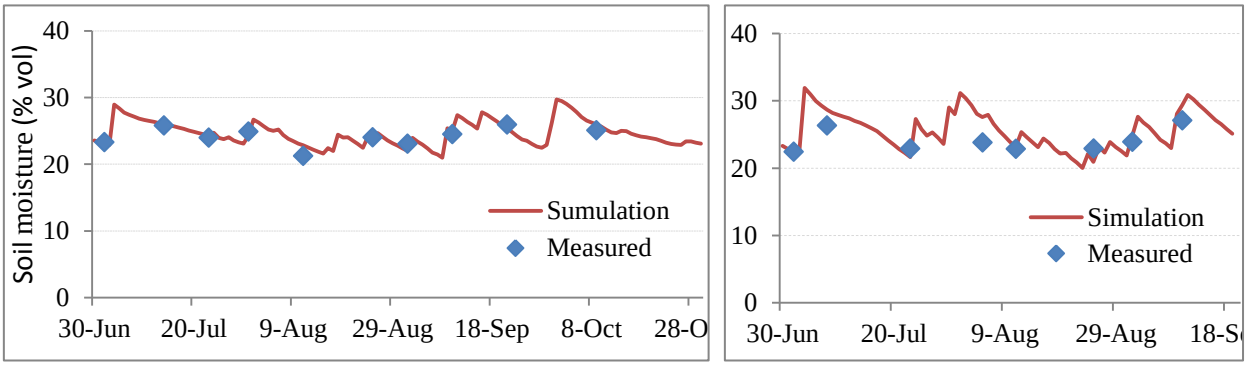

Figure 3. Left: Measured soil moisture and simulation of soil moisture under succession soybeans, at a depth of 0-0.8 m. Right: Measured soil moisture and simulation of the humidity of the soil under the succession green beans, at a depth of 0-0.5 m, in the experimental field in Zemun Polje

Measured and simulated soil moisture under succession soybeans were in a similar range. The measured values were from 21.2 - 25.9% vol., and simulated from 22.0 - 26.0% vol. In the case of soil under green beans, the simulation showed a higher range of values (20.9-29.4% vol) compared to the measured values (22.4-27.1% vol). Mkhabela and Bullock (2012), have concluded that the model tended to slightly underestimate the soil water at high water content in wet conditions and overestimate it at low soil water contents during dry years using the FAO AquaCrop model for simulation of total soil water content (0-120 cm layer) in the field under wheat. Similar results came from Paredes et al. (2015), comparing the results from a four-year experiment of the soybean growing in North China Plain with simulated soil moisture results obtained by the AquaCrop model. Our research can not confirm this conclusion, since the measurements always show the moderate humidity of the soil (Figure 3). At no time there was no high moisture content, nor the large water deficit registered.

The estimation of the concurrence of the measured and simulated soil moisture values was made using the statistical parameters: the Willmott index of agreement (d), absolute and normalized root mean square error (RMSE, nRMSE) and the correlation coefficient (R) (Table 2).

Table 2. - Evaluation of the agreement of simulations and observed (measured) soil moisture data under succession soybean and green beans in the experimental field in Zemun Polje (n - number of observed data)

	Willmott d	RMSE	nRMSE	R	n
Soybeans (0-0.8m)	0.90363	0.793465	3.2817	0.8231	10
Green beans (0-0.5m)	0.821808	1.995971	8.3079	0.8897	8

Based on the Willmott index of agreement (d), the conformity of the measured and simulated values of soil moisture obtained by the Aquacrop model is better in soybean (d=0.90363) than in the green bean (d=0.821808). The calculated values of RMSE and nRMSE, were 0.79% and 3.28% for soybean; 2% and 8.31% for green bean, respectively. In both cases simulation is considered as excellent (nRMSE is less than 10%). The correlation coefficient shows a high degree of agreement of the results and it is 0.82 for the soil under the succession soybean and 0.89 for the soil under the succession green beans.

The evaluation of the AquaCrop model at different location, indicated that the model was able to simulate soil moisture of root zone accurately (Andarziana et al., 2011; Xiangxiang et al., 2013; Mkhabela and Bullock, 2012).

Conclusion

Testing of the FAO AquaCrop model, on two irrigation fields sowed by succession soybean and succession green beans, showed good agreement between measured i.e. observed and simulated soil moisture values. It can be concluded that the FAO AquaCrop model can be successfully used for predicting the moisture of chernozem on the loessial terrace of the Zemun Polje, for the purposes of determining the irrigation regimen of succession crops. However, since the research was carried out during the one vegetation season, with a relatively small number of observed data, this finding should be confirmed by the results of the research during several more vegetation seasons.

Abstract

Maize (*Zea mays* L.) is the highest ranking crop in terms of area and production in Serbia. During the whole growing period maize requires high temperatures and sufficient amounts of precipitation. High yields could be achieved on loose and porous soil with good capacity for water and those containing easily-accessible nutrients. The agro-ecological conditions for maize production differ over various regions of Serbia and meteorological parameters can seriously influence maize cultivation. Natural hazards, such as the occurrence of frosts, heavy rains in spring, floods, storms, hail, droughts, cause stress and to a significant degree can reduce or destroy maize yields. The application of appropriate cropping practices mitigates adverse effects of climate and soil and provides conditions for the maximum utilisation of the genetic yielding potential of maize hybrids. A system of measures that encompasses proper crop rotation, primary soil tillage, fertilisation, sowing date and density, irrigation, as well as some ecological measures such as intercropping or cover crops, are basic prerequisites for successful production of maize in Serbia. Many producers do not use these measures at the appropriate level even though results shows that fertilisation can improve maize yields from 7.87 t/ha to 10.00 t/ha under rainfed and from 9.42 t/ha to 12.32 t/ha under irrigated conditions. Irrigation can also increase maize yields by more than 30%. In the study, good agricultural practices as components of an improved technologies that could help to reduce the impacts of natural hazards and obtain high and stable yields, are identified and validated.

Key words: *Maize, Cropping practices, Yield, Natural disasters, Drought*

Introduction

Of a total of 5 million ha of agricultural land in Serbia, 3.3 million hectares are arable land. Maize is traditionally grown on 1.2 or even 1.3 million ha, but in 2018, maize was sown on about 0.9 million ha (http://www.zitasrbije.rs). Maize hybrids with the genetic potential of 10-15 t ha^{-1} have been grown for over 40 years in Serbia, but yielded 5.5 to 6.5 t/ha in average (Videnovic et al., 2013b). The main reasons for such a difference are drought; soils that are not suitable in the same degree for intensive production; the insufficient application of mineral fertilisers, outdated machinery and small and fragmented arable farms (Kovačević et al., 2012a; Videnović et al., 2013b). Drought often occurs, particularly in Eastern Serbia and only 1/3 of the total maize/soybean production is carried out on favourable soils; the irrigation is applied in only 2% of the maize production areas. Despite this, the Republic of Serbia is a significant producer of cereals within the European frames and the largest regional producer of maize with an average production of about 6 million tons (Statistical Office of the Republic of Serbia, http://webrzs.stat.gov.rs/WebSite/public/ReportView.aspx).

The effects of climate change, which affect the Western Balkans include increased temperature, reduced total precipitation, increased number of summer days, extended period between the last spring and first autumn frost, increased sum of active air temperature above 10 °C, etc. (Čustović et al., 2012; Kovačević et al., 2013). Drought is a multidimensional stress affecting photosynthesis and maize growth. No other environmental factor limits global crop production more severely than water deficit and it is the most important abiotic stress

that seriously decreases the final grain yield of maize (Videnović et al., 2013a). In addition, heavy rains, floods, storms, hails, as well as, extremely low and high temperatures, can cause stress and may, to a significant degree, reduce or destroy the yield of maize (Kovačević et al., 2012b). According to the 2015 World Risk Index, the exposure of the population in the Western Balkan countries to such hazards is the highest within the European region.

Maximum yield achievement is still the main strategy in agriculture and could be reached by innovative research orientated towards better understanding of soil-plant relations within the agro-ecosystem, maximum utilisation of the genetic potential of new genotypes and optimisation of cropping technology (inputs-outputs) in regard to climate changes (Byerlee et al., 2014). Crop growing practices can give advantages to the growing plant to maximise its genetic potential in years with regular and extreme conditions (Dragičević et al., 2015). It is very important that maize plant is well-supplied with moisture until the end of flowering, during the cob formation, and grain filling (Kovačević et al., 2013). In the fight against drought, regular and specific cultural practices could be used along with irrigation as the most direct practice by which water can be added in desired quantities independently of precipitation and with far-reaching effects (Kovačević et al., 2012a). The economic effect of climate changes on agriculture requires different practices for rain-fed (Schlenker et al. 2002) and for irrigated regions. In dry land farming areas, climate changes are equivalent to an exogenous shift in the fixed input associated with new supplies. In irrigated regions, the local climate is not directly connected to water supply. A risk reduction present in forecasting is a necessary part of any cropping practice (Iglesias et al., 2011).

Cropping technology determines the effectiveness of certain cultivation measures on morphological and productive traits of the crop, as well as effects of some components of the agro-environmental complex such as weeds and insects. Variations in cropping practices enable environmental factors to be overcome. A cropping practices that can help in overcoming the negative influence of climate changes on maize production and increase grain yield includes crop rotation, soil tillage, fertilisation, irrigation, sowing time and density, appropriate choice of hybrids, intercropping, cover crops, etc. (http://www.fao.org/3/I8848RS/i8848rs.pdf). In the three-crop rotation system with soybean as a legume crop, maize grain yield was higher by 11.4% than in the three-crop rotation system with winter wheat (Videnović et al., 2013a); conventional soil tillage that includes autumn ploughing at a depth of 25 cm or more resulted in the highest ten-year average maize yield of 10.61 t/ha (Videnović et al., 2011); fertilisation is one of the most important aspects in increasing yield and its stability (Berzsenyi et al., 2000; Varvel, 2000); sowing should be done earlier in case of drought and with a proper density for each hybrid (Kresović et al., 2011); irrigation needs to be conducted with adjusted norms in respect to the soil moisture and monthly water needs of maize (Kresović et al., 2013). Moreover, some ecological measures, such as intercropping or cover crops contribute to higher yield achievement (Dolijanović and Simić, 2016; Janosevic et al., 2017). Previous investigations also showed that soil moisture was slightly higher during anthesis under no-till in rain-fed cropping in relation to conventional and reduced tillage (Dragičević et al., 2012). All of the listed practices are basic prerequisites for successful production of maize in Serbia, but many producers do not apply these measures at the appropriate level even though results show that they are effective. Research results of good agricultural practices and improved technologies that could help producers to reduce the impacts of natural hazards and obtain high and stable yields are presented in the manuscript.

Material and Methods

Effects of various cropping practices on maize production have been observed within a long-term research program of experiments that have been carried out in the fields of the Maize

Research Institute, Zemun Polje. Maize was cultivated in different crop rotations, soil tillage systems, under recommended and altered densities, with application of cover crops and within intercropping systems, as well as with and without irrigation. Standard grain quality hybrids were grown with modified sowing densities and the application of organic, mineral and microbiological fertilisers, and various forms of mineral nitrogen.
The soil type in the experimental field was slightly calcareous chernozem with 53% sand, 30% silt, 17% clay; with good fertility and 3.3% of organic matter content and moderate drainage. The pH was 6.9 and soil structure was a silty clay loam. The meteorological conditions varied during and between the seasons as evident through results.
Maize grain yield was the main parameter that was evaluated. This parameter was estimated in the two inner rows and then calculated to 14% moisture.

Results and discussion

The cropping systems were basically defined by **crop rotation** which means proper arrangement of crops in time and space to better utilise soil potentials and climate (Kovačević, 2010). The crop rotation improved soil physical and chemical properties, contributed to biodiversity by growing different crops and genotypes, and influenced the composition and structure of field weed communities (Dolijanović and Simić, 2016). Rotation sequences with row and dense crops, legumes and cereals, also included rotation of cropping technologies and herbicides with different modes of action (Simić and Dolijanović, 2016). Efficient crop rotation encompasses crops with deep and shallow root systems, crops that uptake large quantities of nutrients and crops that enrich the soil, crops that extract and consume large amounts of water from the soil vs. crops that accumulate and maintain the water in the soil.

Table 1. Efficacy of crop rotation in maize cultivation (grain yield), Zemun Polje, 1998-2015

Cropping systems	Fertiliser level				Average
	F1	F2	F3	F4	
Continuous maize	3.89	6.39	6.69	6.90	5.97
Maize - Soybean	6.95	7.99	7.80	7.66	7.60
Maize - Winter wheat	6.33	7.67	7.81	7.66	7.37
Maize - W. wheat - Soybean	8.01	8.78	8.77	8.65	8.55
Average (t ha^{-1})	6.29	7.71	7.77	7.72	7.37

F1 - 0 kg ha^{-1} NPK; F2 - 180 kg ha^{-1} NPK; F3 - 270 kg ha^{-1} NPK; F4 - 360 kg ha^{-1} NPK

In Serbia, maize is grown on approximately 70% of areas after small grains, usually winter wheat (Videnović et al., 2013a). These crops are good preceding crops, as they are dense and inhibit the development of weeds and there is also enough time after harvest for summer and autumn tillage. Continuous cropping or maize monoculture is applied on approximately 20% of arable areas in Serbia. It brings higher infestations with perennial, especially grass weeds potentially resistant to herbicides, and increased damage caused by western corn rootworm. For these reasons, this system is not spreading and in some regions its application even declines. Maize is grown on about 10% of areas in which soybean was a preceding crop which is a very important advancement in the improvement of maize growing practices in Serbia; it is well-known that soybean is one of the best preceding crops for maize, Table 1. Results from investigations showed that presence of plants from the family *Fabaceae* significantly contributes to the efficiency of crop rotation through the reduction of mineral nitrogen fertilisers by 50%, maize yields increase, accompanied by soil preservation and improvement (Videnović et al., 2013a; Jovanović et al., 2004). A cropping system such as

double-crop rotation of maize and winter wheat and three-crop rotation of maize, soybean and winter wheat influences maize plant height and grain yield after only one rotation in comparison with maize continuous cropping (Spasojević, 2014; Simić et al. 2017). In years with unfavourable conditions for maize production, the beneficial effects of the crop rotation are even more pronounced.

Soil tillage supports efficient water use and prevents erosion, increases crop competitiveness, reduces the concentration of CO_2 and soil compaction and gives better texture etc. In most production regions in Serbia, a variety of measures such as proper tillage and fertilisation, autumn ploughing, summer ploughing etc., are employed to collect and store moisture in the soil. Maize plants can use the stored water during periods of drought. It is well known that accumulated water increases maize yield.

Recently, systems of reduced tillage, particularly direct sowing, have entered into widespread use (Fulton, 2010). In dry years and on chernozem as a rich and quality soil, no-till could be an effective measure for soil moisture preservation in relation to conventional and reduced tillage (Dragičević et al., 2012). The effectiveness of reduced tillage systems should be tested for other types of soils and agro-ecological conditions in Serbia. However, these systems require the implementation of measures for intensive weed control (herbicides).

Table 2. Effects of soil tillage on maize grain yield (t ha^{-1}), Zemun Polje, 2000-2013

Tillage system	2000	2001	2002	2003	2004	2005	2006	2007	2008	2009	2010	2011	2012	2013	Average
No till	3.0	6.0	8.5	6.0	11.5	8.9	8.0	6.4	3.9	11.6	8.1	6.7	2.8	5.5	6.9

Average	5.7	7.7	9.2	7.4	12.9	11.7	10.3	7.4	6.6	11.7	9.1	8.4	3.2	7.3	8.5

Under the agro-ecological conditions of Serbia, the highest maize yields and the most efficient weed suppression, especially perennial, are achieved by using a conventional soil tillage which is also most suitable in regard to changeable climatic conditions. In average for fourteen years, conventional tillage contributed to higher yield of maize for 1,5 t/ha and 3,1 t/ha in comparison to reduced and no-till under agro-ecological conditions of Zemun Polje, Table 2. The conventional tillage includes ploughing in autumn (20-25 cm) - soil remains in the form of open furrows to freeze during winter; a single pass land preparation is applied in spring - shallow tillage 10-12 cm. In such a way a good soil structure is provided, moisture is maintained, the soil is not trampled, and weed seedlings are destroyed, which is all of particular importance for efficient herbicide actions.

Fertilisation provides the necessary elements for growth and development of maize. Fertilisation with manure improves soil properties, particularly water - air capacity, which is especially evident when plants are exposed to stress in conditions of natural disasters (Simić et al., 2016a). The application of mineral fertilisers to maize can be managed by time, place and amount of fertilisers (Liu and Wiatrak (2011). Fertilisation changes the relationship in crop competition to weeds, not only for nutrients, but also for other resources, so it is essential that the optimal quantity of fertilisers is provided to the plant at the right time and at the place from which it will best be used (Simić et al., 2016b). The most intensive and the highest rate of nitrogen intake occurs at the beginning of the growing season, and in the period of flowering, respectively. After the start of the milk grain stage, the absorption of nitrogen

slows down. Phosphorus is taken by plants in significantly smaller amounts than potassium and nitrogen, in the period of tillering until the beginning of flowering. Potassium is most quickly absorbed from the soil during germination and the formation of tillers. On heavy and substantially sandy soils, maize responds very well to manure fertilisation. Application of mineral fertilisers in maize cultivation can contribute to obtaining higher yields, under rain-fed and especially irrigated soils, Table 3. In Central Serbia, soils are porous with a good water availability, but recently the climate has altered towards an increased frequency of drought years. The use of N fertilisers with inhibitors may reduce the risk of environmental N loss associated with application of conventional N fertiliser sources under variable-climatic conditions (Simić et al., 2016c). The highest yield of a late-maturing hybrid in the experimental plot with long-term continuous cropping (over 35 years) was achieved when manure was applied, harvest residues ploughed down completely and N fertiliser applied in spring at the beginning of the growing season (Simić et al., 2013).

Table 3. The influence of fertiliser level on maize grain yield (t ha^{-1}) in different soil tillage systems, Zemun Polje, 2000-2017

	No till	Reduced tillage	Convent. tillage	Average
		Rainfed		
F1 - 0 kg NPK	5.84	7.39	10.39	7.87

Average	9.47	10.87	13.00	11.12

Irrigation helps to reduce the impact of soil and air drought on maize. This concerns the application of water in controlled quantities and certain intervals to the soil or plants to support the optimal growth and development of crops. The achievement of high yields under conditions in Serbia is limited by two factors: - the uneven distribution and deficit in precipitation. In Serbia, six of ten years are dry (extreme to moderate and weak drought), two years have moderate conditions and two are optimum for maize production. In the case of maize, the critical period begins 15–20 days prior to tasselling and lasts until the beginning of the milk stage. When the years are average in terms of weather conditions, maize production under irrigation conditions will result in higher yields by 15-30% or even by 50% in seed maize production (Simic et al., 2016d). Irrigation provides the optimum water supply, activates soil microorganisms and nutrient reserves, and contributes to a better utilisation of incorporated fertilisers.

Sowing and crop density - Maize sowing involves several operations (selection of hybrids, preparation of seed for sowing, sowing time, sowing depth, number of plants per ha, i.e. sowing density, and plant arrangement). High yields of today's maize hybrids can be obtained only if the necessary number of plants is sown per area unit: 70-80,000, 60-70,000 and 60,000 plants ha^{-1} for hybrids of FAO 300-400, FAO 500-600 and FAO 700, respectively.

The sowing time and density are important because they affect crop biomass, lodging, efficiency of nutrient use, harvest time, etc. The optimum sowing time of maize should be harmonized with weather forecasts for a given year, with particular reference to the possible occurrence of drought, floods, etc. Late sowing does not give satisfactory yields, especially in

no-irrigation conditions, and in the case of FAO 600-700 hybrids. In such conditions, it often happens that later FAO groups do not complete their vegetation.

Producers in the regions with frequent occurrence of drought such as Banat, East Serbia and South Serbia, usually grow hybrids with shorter vegetation, FAO 300-400 or FAO 500, with 115-125 days of vegetation period. In dry years, it is more efficient to conduct early sowing at the beginning of April with maximum density of 55-65,000 plants/ha and adapt cropping technology to dry conditions.

A B

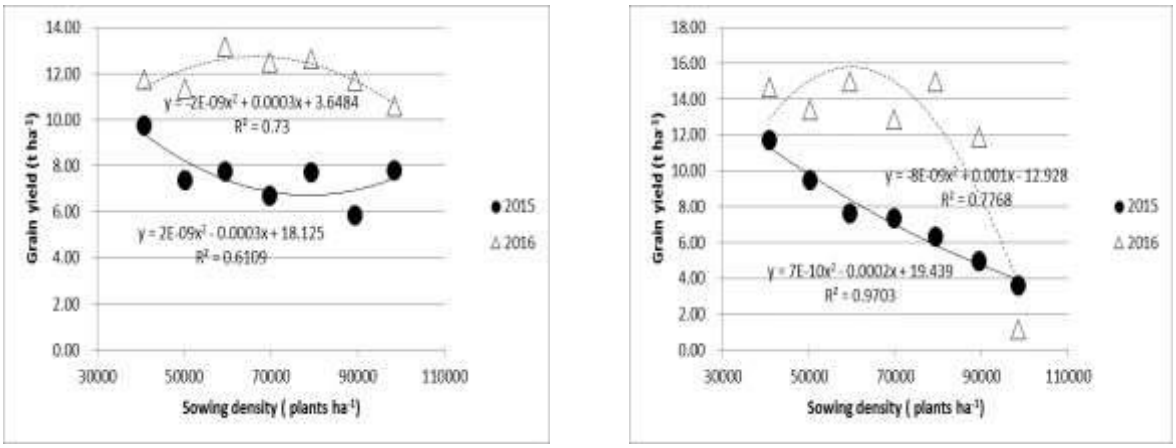

Figure 1. Average yields (t/ha) of maize hybrids of different FAO groups – ZP 366 (A) and ZP 606 (B) in different sowing densities under irrigation conditions (2015-2016 in Zemun Polje)

Increasing the number of plants per hectare up to a certain extent increased the grain yield of maize, but once this limit was achieved the yield decreased. This is, for both hybrids, particularly observable in 2016, a very favourable year for maize production. In this year, yield slowly decreased only when maize was sown in very high densities (more than 70,000 plants per ha), Figure 1. On the other hand, in the dry 2015 year, increased plant density lead to the reduction of grain yield of maize hybrids. The intraspecific competition occurs when the number of maize plants per ha increases and the full yield potentials are manifested only in good years, such as 2016. The impact of meteorological conditions in some years could be very important and similar results were presented for other years, which were not optimal regarding precipitation (Kresovic et al., 2011).

Maize hybrids with a rapid initial growth rate are more competitive than the other hybrids and, a careful selection of competitive hybrids can dramatically reduce grain yield losses and weed biomass, as well as seed production (Simić et al., 2009; Travlos et al., 2011).

Cover crops and intercropping - The cultivation of cover crops is a special way of overlaying/covering the soil. Thus cover crops contribute to the sustainable management of soil structure and soil functioning for water infiltration and storage in crop production (Bodner et al., 2014). Cover crops reduce the runoff/leaching of nutrients from the soil and increase the content of organic matter and they should be cultivated to preserve the fertility of the soil. In a study recently conducted in Zemun Polje, sweet maize yield was highest after a fodder kale and field pea cultivation, but smallest after winter oat and common vetch as cover crops. Different autmn-winter cover crops and microbiological fertiliser showed more efficiency in the dry year on nitrogen utilisation in the soil and sweet maize yield (Janosevic et al., 2017).

Inter-cropping provides greater stability and diversity of production and better use of nutrients, light, heat, air, and vegetation space. Maize can successfully be intercropped with legumes (soybeans, beans and lupines). The choice of genotype in intercropping depends on

the aim of the cultivation. For stock production, usually specific maize hybrids are grown that would be most productive in intercropping with soybean. However, in addition to numerous advantages, this cropping system encounters numerous limitations (e.g. mechanical sowing and harvesting, weed control), which prevent its greater application in practice. Despite this, many results suggest that intercropping is a potential strategy to increase agro-ecosystem preservation by enhancing crop production, improving soil quality and mitigating greenhouse gas emissions (Dolijanović and Simić, 2015).

Conclusion

Based on the analysis of many results it could be concluded that maize production in Serbia significantly depends on meteorological conditions. Genetic potential of maize hybrids was not used enough. Good agricultural practices within maize cropping technology proved in the experimental work must be implemented in order to increase maize yield. In regard to present climate changes, precipitation deficiency is the main limiting factor in maize production in Serbia, so the irrigation is one of the most important measures which could contribute to significant maize production improving. All recommended practices contribute to the crop withstanding negative effects of climate changes and maintaining yield and grain quality with the least possible adverse consequences. Recommendations for their application are particularly emphasised when certain natural hazards are expected or it is known that they will occur.

Abstract

This study was conducted to determine some quality traits of silage corn (*Zea mays* L.) after Hungarian vetch (*Vicia pannonica* Crantz) intercropping with barley (*Hordeum vulgare* L.), wheat (*Triticum aestivum* L.) and triticale (*Triticosecale* Wittmack) sown at different mixture rates (100:0 70:30, 60:40, 50:50 and 40:60%) and cut at the flowering and milk dough stages in the ecological condition of Yozgat during 2014 and 2015 growing seasons. The experiment was arranged in split plot-design with four replications, main plots were sowing time and sub plots were previous crop (mixture rates). Crude protein ratio and crude ash ratio, ADF, NDF, K, P, Ca and Mg contents were determined. Crude protein and ash ratio were ranged between 5.90 – 7.75% and 6.18 – 7.38% of respectively. The lowest ADF and NDF ratios were determined sole barley (34.19 – 61.38%), while the highest were determined 50HV:50T% (36.88 – 65.99%). K, P, Ca ve Mg contents of silage corn were ranged 1.96 – 2.17%, 0.271 – 0.289%, 0.23 – 0.30% and 0.18 – 0.22% of respectively. According to two years results, it has been determined that it is decreases quality when delayed silage maize sowing time and also, some corn plots that were planted after the Hungarian vetch + cereal mixtures of previous crop are not difference to stubble plot in terms of hay quality.

Key words: *Pre-plant, sowing time, quality, silage corn*

Introduction

In the crop rotation, first sown plant is previous plant (pre-plant) and second sown plant is following plant. The effect of the pre-plant to following plants is called the pre-plant effect. Each following plant demands precious sowing time and growing condition from the pre-plant. The effect of the pre-plant to following plants is called the pre-plant effect. The pre-plant effect is affected by climate, soil and environmental factors and the long or short duration of the vegetation. The length of the vegetation period is important for legumes. Because, legumes fix nitrogen and organic matter to soil and also improve the structure. Legumes affect the yield and quality of following plants. Kavut and Geren (2005) reported that legumes supply nitrogen for corn and increase of their yield. Therefore, legumes are very good pre-plants for corn.

Silage corn has a great importance for feeding ruminants, such as cattle. Corn is use intensively in silage production and it is constitute approximately 80% of silage production in Turkey (Dumlu and Tan, 2009). Silage corn can be planted as main and double crop, planting time show the differences year by year according to the climatic conditions and pre-plant harvest time, therefore especially silage quality, plant development and plant nutrient contents show differences (Oten, 2017).

This study was aimed to determine some quality traits of silage corn (*Zea mays* L.) after Hungarian vetch + cereal intercropping sown in the ecological condition of Yozgat during 2014 and 2015 growing seasons.

Material and Methods

This study was conducted to determine some quality traits of silage corn after Hungarian vetch (HV) intercropping with barley (B), wheat (W) and triticale (T) sown at different mixture rates (100:0 70:30, 60:40, 50:50 and 40:60%) and cut at the flowering (first sowing time) and milk dough stages (second sowing time) in the ecological condition of Yozgat during 2014 and 2015 years.

Soil properties of the experimental area of both year were clay –loam type with pH of 8.20-8.12 and 7.93-7.99% CaCO3, 86.2-82.1 kg ha^{-1} phosphorus, and 1.98-1.78% organic matter at the depth of 30 cm (Table 1).

Table 1. Physical and Chemical Properties of Soil in Research Area*

Properties	2014	2015
Structure	Clay-loam	Clay-loam
CaCO3 (%)	7.93	7.99
Total salt (%)	0.018	0.020
P_2O_5 (kg ha^{-1})	86.2	82.1
K_2O (kg ha^{-1})	484.7	454.7
Ph	8.20	8.12
Organic matter (%)	1.98	1.78

*LTM: Long term mean; ** Tukish State Meterogical Service

Firstly, Hungarian vetch and cereals (Barley, Wheat and Triticale) were sown as binary mixtures with different seed rates (100:0%, 70:30%, 60:40%, 50:50% 40:60%) and harvested at the flowering and milk dough stages. Then silage corn (*Zea mays* L. "Cadız") was sown. The experiments were arranged in split plot design with four replications, main plots were sowing times and sub plots were previous crop (mixtures). The sowing was done manually after harvesting of hungarian vetch: cereal mixtures. Plot size was 5 x 1.5 m = 7.5 m^2 and distance between rows was 50 cm. Also Hungarian vetch: cereals mixtures were comparison stubble as a control. Plant density was 120.000 seed for per hectare. The full dose nitrogen (50 kg N ha^{-1}), phosphate (80 kg P_2O_5 ha^{-1}) were applied at sowing time. Additional nitrogen fertilizer (50 kg N ha^{-1}) was applied at the stage when the plants were 40-50 cm. In the study, silage maize was irrigated five times and weeds were controlled by hoeing. Silage corn was harvested in dough stage.

Plant samples were dried 65 °C until constant weight to determine their hay yield. Crude protein, ADF, NDF, K, Ca, P and Mg contents of hay were determined by using Near Reflectance Spectroscopy (NIRS, 'Foss 6500') with software package program 'IC-0904FE'. Data were statistically analysed by repeated measure analysis in MSTAT-C statistical programme and means were separated by Duncan's Multiple Range test.

Results and Discussion

According to combined years, in terms of crude protein ratio there was significant difference ($p \leq 0.01$) between sowing time and previous crop, while it was not significant sowing time*previous crop interaction and years (Table 3). Crude protein ratio was ranged 5.90% (previous crop 50HV:50W%) – 7.75% (Stubble). Parlak and Sevimay (2007) reported that crude protein ratio of silage corn, grown after barley and wheat, was 7.23%.

The lowest crude ash ratio was 6.18% (previous crop 40HV:60T%), while the highest was 7.38% (previous crop 70HV:30W%) (Table 3). Some silage corn samples after previous crop had more crude ash ratio than hay stubble plots (Table 4). This can be due to the previous crop that can supply nutrients to silage corn.

(*) 0.05, (**) 0.01; FST: First sowing time; SST: Second sowing time; HV: Hungarian vetch; B: Barley, W: Wheat; T: Triticale

The highest ADF content was determined 36.88% (previous crop 50HV:50T%), while the lowest was 34.19% (previous crop 100B%). NDF content was ranged 61.38% (previous crop 100B%) – 66.18% (previous crop 60HV:40W%) (Table 4). Previous studies, ADF and NDF content were ranged 24.22% – 43.29% and 48.11% – 73.85% of respectively (Balmuk, 2012; Carpıcı, 2016).

Stem ratio, cellulose and hemicellulose accumulation in cell wall are increase with the progress of sowing time. This can be occur due to the short vegetation period and high temperature (Buxton ve Casler; 1993; Tan and Mentese, 2003). Therefore, crude protein ratio,

crude ash ratio, ADF and NDF content of the plants for the second sowing time were higher than the first sowing time (Table 3 and 4).

The potassium (K) content was ranged 1.96% (previous crop 50HV:50W%) – 2.17% (previous crop 100T%). On average, K content of silage corn that observed most of the sites is at satisfactory level for dairy cows (NRC, 2005) (Table 5). Different researches reported that silage corn K content was ranged 1.33% – 2.97% (Erdem, 2011; Ozata at al., 2012).
According to combined years, the highest phosphorus (P) content was determined as 0.289% (previous crop 100B%) while the lowest was 0.271% (previous crop 60HV:40W%). NRC 0.2% phosphorus level is meet the demand of cattle (NRC, 2005). On average, the content of P in silage corn in all treatments is above the specified limits (Table 6). Erdem (2011) and Ozata et al. (2012) reported that silage corn P content was ranged 0.120% – 0.260%.
Silage corn Ca content was ranged between 0.23% (previous crop 50HV:50B% and 100T%) – 0.30% (previous crop 70HV:30W%) (Table 6). Average Ca content of the first sowing time was higher than the second sowing time. Ozata et al. (2012) reported that silage corn Ca content was ranged from 0.17% to 0.37%.

(*) 0.05, (**) 0.01; FST: First sowing time; SST: Second sowing time; HV: Hungarian vetch; B: Barley, W: Wheat; T: Triticale

The lowest Mg content was 0.18% (previous crop 50HV:50B%),while the highest was 0.22% (previous crop 100B%) (Table 6). The Mg content in all analysed silage corn samples are above the critical limit of 0.1% DM (NRC, 2005).

Conclusion

According to two years results, it has been determined that quality of silage corn decreases when sowing time delayed in Yozgat ecological conditions. Also, some corn plots that were planted after the Hungarian vetch + cereal mixtures of previous crop are not different to stubble plot in terms of hay quality.

Abstract

The autochthonous apple cultivars are the result of a long selection process by human population and edafish, climatic and geomorphological conditions. Many autochthonous cultivars and populations of many species of fruit trees are present in Bosnia and Herzegovina. The paper presents the one-year results of the study influence of cultivars on the total phenols content in six autochthonous cultivarst of apple (Petrovaca, Bjelicnik, Zelenika, Bobovec, Ljepocvjetka and Sampanjka) in Majevica area. The results of the research showed that the highest phenolic content was in the cultivar Ljepocvjetka (542.10 mg GAE/100 g), then in cultivar Bobovec (419.52 mg GAE/100 g) and Sampanjka (345.28 mg GAE/100 g), while the lowest content of phenols was in the cultivar Bjelcnik (247.45 mg GAE/100 g). Based on the results of research, there are significant variations in the total phenols content and there is no regularity in the content change.

Introduction

The autochthonous cultivars of apple are the result of a long process of selection by human and natural conditions. There are many autochthonous cultivars and populations of many species of fruit trees in Bosnia and Herzegovina, thanks to the diversity of its edafish, climatic and geomorphological conditions. The most of the orchards of old cultivars neglected, but it is necessary to restore and protect, because it gradually create a market for their fruits.

Old cultivars represent a rich source of genetic material, but some cultivars also have very positive properties (eg. high and regular yield), which is very important from the aspect of growing (Mitre et al., 2009), and can have a significant role in selection in the future.

Most of traditional cultivars have a balanced composition of nutrients and bioactive components (Feliciano et al., 2010) and some of cultivars, usually, contain larger amounts of certain compounds, such as total phenols and flavonoids (Veberič et al., 2005) which gives them characteristic properties of color, aroma and taste. The fruit of apple contains several phenolic compounds, and also possesses a high total antioxidant capacity (Lotito & Frei, 2004; Biedrzycka & Amarowicz, 2008). The content of total polyphenols and antioxidant activity depends on cultivar, agroecological contitionals, maturity of fruit, exposure to sunlight, storage and ways of processing (Van der Sluis et al., 2001; Alonso-Salces et al., 2004). The apple is in second place by antioxidant activity and second place (immediately after cranberry) at the total concentration of phenolic content in United States of America (Boyer & Liu, 2004). The aim of the paper was to determine the phenolic content in six autochthonous cultivars of apple from the Majevica area and based on their positive results, their remarkable nutritional potential, based on the high content of natural antioxidants (Ding et al., 2006; Tulipani et al., 2008). There is a large number of studies which relate to the analysis of nutritional and other components in fruits of apple, but it was of particular importance to establish the deviations, ie the correlation of the obtained results with the literature data, because it will use autochthonous cultivars from the Majevica area for which such data are not yet fully available.

Materials and Methods

The research of phenolic content of autochthonous cultivars of apple (Petrovaca, Bjelicnik, Zelenika, Bobovec, Lijepocvjetka and Sampanjka) from the Majevica area in Bosnia and Herzegovina was carried out during 2017. The fruit of cultivars (meat + epidermis) was used to determine the influence of cultivar on total phenol content. The fruits for research were taken in the period of their full maturity from old apple trees placed at several locations.

Total phenolic content assay was conducted using the Folin-Ciocalteu reaction (Singleton et al., 1999), with gallic acid as the standard. The method is based on the measurement of the reducing capacity of polyphenolic compounds whose dissociation results in proton and phenoxide anion. The phenoxy anion reduces the Folin Ciocalteu's reagent to-blue colored ions $(Fenol\text{-}MoW_{12}O_{40})^{4-}$. The reaction mixture was prepared by mixing the fruit extract (0.1 cm^3), 7,9 cm^3 distilled water, 0,5 cm^3 Folin Ciocalteu's reagent and 1,5 cm^3 20% Na_2CO_3.

As a blank test a mixture was used in which 0.1 cm^3 of distilled water was added instead of 0.1 cm^3 of the sample. After incubation at room temperature for two hours, the optical density of the solution at 760 nm was measured. Total phenolics was expressed as mg of gallic acid equivalents (GAE) per kilogram of fresh weight of edible part of fruit (Amerine & Ough, 1980). The results were processed statistically using the analysis of variance. The significance of differences between mean values was evaluated using Duncan's multiple range test for significance level of 0.05. Data analysis was performed using the statistical software package IBM SPSS Statistics 20 (SPSS Inc., Chicago, IL, USA).

Results and Discussion

According to Jakobek & Barron (2016) ecological factors such as temperature, light, humidity, but also and the applied method of extraction significantly influence on the total phenols content in the fruit. The cultivar has an influence on the content of phenols in fruit (Anttonen & Karjalainen (2008). According to these authors, the fruits of cultivars, which grown under the same conditions, are significantly different in total phenolic content.

Tabart et al. (2006) state that the content of phenolic in fruits of apples depending on the genotype, the conditions during maturing, the moment of harvest, but also treatment with fruits after harvest. The phenolic content have a significant influence in the resistance of the cultivar to Venturia inaequalis (Cooke) Wint. According to Usenik et al. (2004), the total phenols content in plant tissues affects the level of susceptibility/tolerance of genotype of apple to fungal infections and pathogens. Treutter & Feucht (1990) state that the content of total flavanols in the epidermis of the fruit resistant cultivars of apple was three times higher than the cultivars of apple susceptible to this pathogen.

The fruit of six autochthonous cultivars (meat+epidermis) was used to determine the influence of cultivar on total phenol content and the results of these studies were presented in Table 1.

Table 1. The total phenols content in fruit of cultivars of apple from Majevica ara

Cultivar of apple	**Total phenols content (TP mg GAE/100 g FW)**
Petrovaca	276,41 ± 1,15 **a**
Bjelicnik	247,45 ± 1,31 **a**
Zelenika	306,80 ± 1,17 **b**
Bobovec	419,52 ± 1,52 **c**
Ljepocvjetka	542,10 ± 1,12 **d**
Sampanjka	345,28 ± 1,11 **ab**

**1mg of gallic acid equivalents (GAE)/100 g FW; **Mean values followed by the same letter within a column do not differ significantly according to Duncan's multiple range test at P≤0.05.*

The results of research show that the highest phenolic content was in cultivar Ljepovjetka (542.10 mg GAE/100 g) than in cultivar Bobovec (419.52 mg GAE/100 g) and cultivar Sampanjka (345.28 mg GAE/100 g). The lowest phenolic content was in cultivar Bjelicnik (247.45 mg GAE/100 g). Using Duncan's multiple range test interval is clearly observed differences in total phenol content in the tested cultivars of apple ($P < 0.05$).

Similar results have also come up and Valvanidis et al. (2009); Li et al. (2013) and other. Oszmianski & Wojdylo (2008) and Ayub Ali et al. (2010) show lower values of the total phenol content. Our results are similar to data reported by the Wolfe et al. (2003), as and authors Escarpa & Gonzaleza (2001). Delian et al. (2011) have determined the lower content of total phenol content in the apidermis of apple, while the higher values of total phenol content was in researches Drogoudi et al. (2008) and Vieira et al. (2009).

Based on the results of this research, as well as the literature data, it can be concluded that there are significant variations in the phenolic content and that there is no regularity in the change content of phenolic. Such variations in the phenolic content in fruit of different cultivars of apples are only confirmed results and conclusions in this research and it is that is cultivar and geographic origin have an important influence on its ultimate phenolic content.

Conclusion

Based on the study of phenolic content of the autochthonous cultivars of apple from the Majevica area, we can conclude the following:

- Autochthonous cultivars of apple during a long period og time have been adapted to the agro-ecological conditions of Republika Srpska and Bosnia and Herzegovina and have economic importance.
- Autochthonous cultivars are a very rich source of genetic variability
- The highest phenolic content was in cultivar Ljepovjetka (542.10 mg GAE/100 g) than in cultivar Bobovec (419.52 mg GAE/100 g) and cultivar Sampanjka (345.28 mg GAE/100 g). The lowest phenolic content was in cultivar Bjelicnik (247.45 mg GAE/100 g).
- Based on the results of these researches, there are significant variations and that there is no regularity in the change content of phenolic.
- Such variations in the phenolic content of different cultivars of apple are only confirmed results and conclusions of our research, and that the cultivar and geographic origin have an important impact on his final phenolic content.

Abstract

Lebanon is one of the oldest sites for wine production in the world. The sector of viniculture is witnessing a general development in the last decades, where more than 65 wineries are found. Worldwide, the reality of climate change being a problem is affecting agricultural aspects by modifying phenological growth of crops. Therefore, in the current study, the performance of the variety Cabernet sauvignon as affected by climate modification was observed during the last decade in the west Bekaa. In fact, the effect of increasing temperature and decreasing precipitation between 2009 and 2017 was tested on dates of budburst, flowering, fruit set and fruit maturity. All dates were calculated considering the first of January as an initial date ($date_0$). As a result, in 2017, budburst, flowering and fruit set occurred earlier by 15 days, 12 days and 28 days respectively compared to 2009. Accordingly, the number of days between beginning budburst and fruit set was later in 2009 (52 days) by 3 days than the one in 2017 (49 days). Consequently, the phenomenon of earliness in all phenological stages was detected on the entire growth cycle presented by the harvest date. This latter was earlier by 23 days in 2017 (262 days after $date_0$) compared to 2009 (285 days after $date_0$). The phenological stages of the variety Cabernet Sauvignon were highly affected by the climate variation occurring in the last years.

Introduction

Intergovernmental Panel on Climate Change (IPCC), in its latest announcement affirmed that the frequency and intensity of drought in the Mediterranean region will possibly increase into the early and late 21st century. The average of precipitation in the eastern Mediterranean region for the period 1986-2005 to 2081-2100 will supposedly decrease between 20% and 30%, also an increase in temperature of 2°C to 3°C (IPCC, 2013).Wet and warmer conditions result in an elongated hot and dry climate. Temperature and precipitation extremes will also increase. The drought periods, will become 9 days longer by 2040 and 18 days longer by 2090 (MoE, 2011).

The connection between temperature and wine production in wine grape growth with conductive climates is supported through historical evidence (Le Roy Ladurie, 1971; Pfister, 1988). In fact, the dramatic decline in temperatures during the "Little Ice Age" (14–19th centuries) led to northern vineyards to die out and to short growth seasons that made grape growth and harvesting extremely difficult in southern Europe. Moreover, geographic and varietal changes on viticulture due to climate change are most likely to be highly variable. Early analysis suggests that European growth seasons will lengthen and that there would be an increase in precipitation in the North and a decrease in the South (Lough et al., 1983). *Vitis vinifera* grapevines are phenologically distinct with defined development stages: budburst, flowering, fruit set, and grape maturity. The timing of each stage varies with grapevine variety, climate, and geographic location. In cool climate regions with short growing seasons,

early ripening varieties are needed, while in hot climates late ripening varieties have sufficient time to mature. Developmental stage timing is related to the ability of the vine to yield fruit, where early and fully expressed phenological events usually lead to larger yields. Furthermore, phenological timing has been found to relate to the quality of the vintage with early harvests resulting in high quality vintages (Jones and Davis, 2000).

Viticulture is an excellent example in showing the importance of studying the effect of climate change on agriculture. Grape growth history has associated fine wines with distinct viticulture regions (Johnson, 1985; Penning-Rowsell, 1989; Unwin, 1991) mainly found in Mediterranean climate regions around the world. Lebanon, being part of the Mediterranean region is characterized by a climate with four different seasons. This encloses a rainy period followed by dryness from November to March. Annual precipitation ranges between 600 mm to 800 mm, 1000 mm to 1400 mm, 200 mm to 600 mm and 600 mm to 1000 mm in the coastal plain, Mount Lebanon, Central and Northern Bekaa and Southern regions respectively (Ministry of Environment/Ecodit, 2010).

Since the Phoenician era, the existence of Lebanese wine has been an ideal example of the country's viticulture. This is a representation of the story-making activity of wine production. The wines and vines of the Lebanese territory have portrayed an indispensible role throughout the Mediterranean. In 2016, this number reached 60 (Roselier, 2016) when a total of 8 million bottles were produced per year.

The most substantial factor in manufacturing great wines is grapes quality, especially when it is associated with a know-how expertise in the professional vinification course. This ensures optimization of the organoleptic expression of the wines and its terroir characteristics. Lebanese terroirs are characterized by plains and hillsides, typical calcareous-clay and stony soils, wetness during winter and dryness in the summer (Mohasseb and Sassine, 2010), 300 days of sunshine, which accommodates flawless maturity and ultimate biosynthesis (Link 1 ; Le Commerce du Levant, 2009). Freshness of wines regardless of the sun and temperature elevation is perpetuated through thermal amplitudes between summer nights and days. This causes the fluctuation of sugars to berries (Navarre and Langlade, 2010).Increase in anthocyanin synthesis through the enhanced reflection of the sunlight is owed to the white color induced by limestone soil copiousness. Different grape varieties could be found in Lebanese vineyards. Each grape variety has its own characteristics, flavor and aromas that could be expressed in the finished wines. The grape varieties planted in Lebanon are mostly noble varieties (LaMar, 2001) as Cinsault, Cabernet Sauvignon, Syrah, Tempranillo, Pinot Noir, Obeidi, Clairette, Chardonnay, Sauvignon Blanc, and Muscat.

Throughout the course of nine consecutive years, our aim was to observe the differences in duration of the phenological stages in West Bekaa as affected by changes in temperature and precipitation between the year 2009 and 2017.

Material and methods

Experimental field

Observations were done in the fields of KSARA winery situated in West Bekaa at an altitude of 1020 meters above sea level, latitude of 33.6406, and longitude of 35.7169 on a surface of 8300 m^2 planted by the variety Cabernet Sauvignon at a 2.5 m × 1.25 m distance between plants and grafted R110 rootstock. Pruning was done using the double Guyot technique leaving twenty buds per vine. Fertilization was done by applying cow manure and organic wastes (plant leaves) in a ratio 50:50 and a dose of 30 Kg/plant.

Data collection

The methods sectioned the season's growth into multiple time periods ranging from each phenological event to the other (budburst, flowering, fruit set, and fruit maturity), where in each period climatic influences were added up and analyzed.

Weekly data collection was performed in order to record the date of each phonological stage on vines that was expressed as number of days after first of January. Phenological stages assessed were dates of budburst, flowering, fruit set and harvest, total production and quality. Records of temperature, relative humidity and precipitations were provided by the Lebanese Agricultural Research Institute (LARI) and soil analysis was performed at the same institute.

Data analysis

A correlation was done among the tested parameters in order to determine positive and negative correlation, using SPSS23 program in addition all graphs were performed applying excel 2007.

Results and discussion

Throughout the previous years, days to full budburst (Figure 1) were as follows: 118 days (in 2009), 109 days (in 2010), 111 days (in 2011), 115 days (2012), 111 days (2014), 115 days (2015), 111 days (2016), and 103 days (2017). This shows that budburst occurred earlier in later years (2016 and 2017) compared to 2009 with the exception of the year 2013 where it was the latest among all years (127 days). The number of days for flowering (Figure 2) declined in 2016 and 2017 (139 and 138 respectively) compared to earlier years mainly 2009 (150 days), 2012 (140 days), 2013 (142 days) and 2014 (143 days) where flowering took place later. With respect to the variety Cabernet Sauvignon, 166 days were needed to obtain the first fruit of the set in 2009. This number was higher than all following years, which required 144, 156, 156, 155, 153, 157, 160, 138 days from 2010 till 2017 respectively. A gradual decrease in number of days to fruit set (Figure 3) was detected over the past 9 years. Similarly, maturity dates (harvest dates) in 2009 (285 days) and 2011 (287 days) surpassed that of the remaining years where it was respectively of 254, 268, 263, 265, 264, 260 and 262 days in 2010, 2012, 2013, 2014, 2015, 2016 and 2017 (Figure 4).

Figure 1: days to full budburst from 2009 till 2017

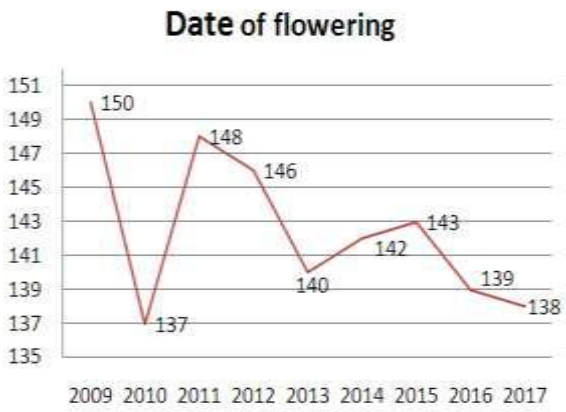

Figure 2: Date of flowering from 2009 till 2017

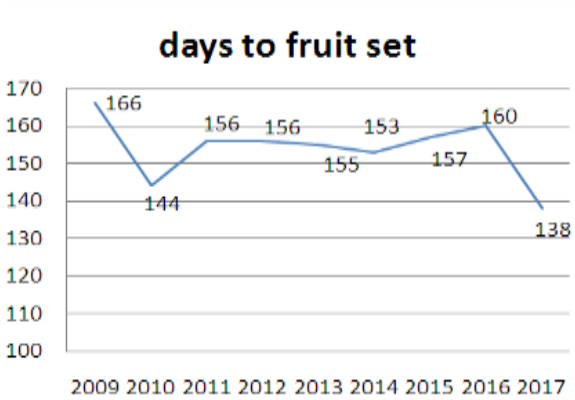

Figure 3: days to fruit set from 2009 till 2017

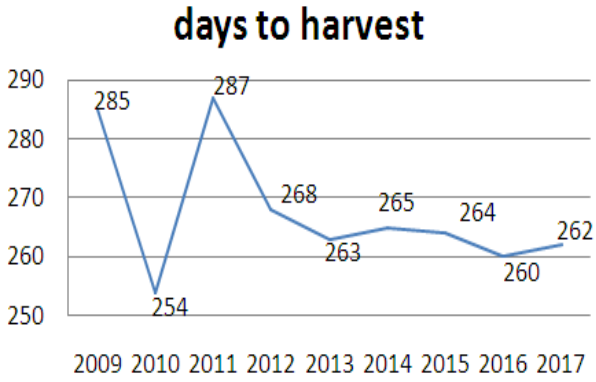

Figure 4: days to harvest from 2009 till 2017

Budburst and flowering shared a decreasing number of days in between them from 2009 till 2017. 36 to 56 days from 2009 till 2016 were recorded, followed by 49 days in 2017. Moreover, there was a mild difference in the number of days between budburst and fruit set in the 9 consecutive years, in which there was a cutback in this number during the first two years (52 days declined to 41 days in 2009 and 2010 respectively). It later escalated to 52 days in 2011, 57 days in 2013 and 59 days in 2014. On the other hand, the number of days between budburst and fruit set in 2015 and 2017 was identical (49 days). However, the highest number of days to fruit set took place in 2016: 77 days. As a result, in 2017, the phenological stages budburst, flowering and fruit set occurred earlier by 15 days, 12 days and 28 days respectively compared to 2009. Accordingly, the number of days between budburst and fruit set was later in 2009 (52 days) by 3 days than the one in 2017 (49 days). Consequently, the phenomenon of earliness in all phenological stages was detected on the entire growth cycle presented by the harvest date. This latter was earlier by 23 days in 2017 (262 days after $date_0$) compared to 2009 (285 days after $date_0$). The phenological stages of the variety Cabernet Sauvignon were highly affected by the climate variation occurring in the last years.

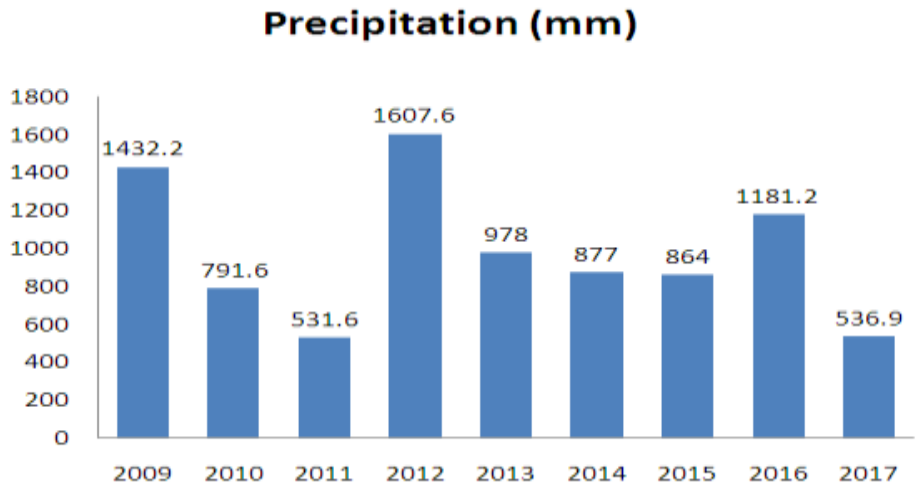

Figure 5: Precipitation levels during 2009 till 2017

Precipitation in Qanafar region varied every year as shown in this graph (Figure 5). It practically began to decline as of 2009 (1432.2 mm), in which precipitation was lower in following years, with the exception of 2012. The latter had 1607.6 mm of rain, while the other years measured 791.6 mm in 2010, 531.6 mm in 2011, 978 mm in 2013, 877 mm in 2014, 854 mm in 2015, 1181.2 mm in 2016, 536.9 mm in 2017.

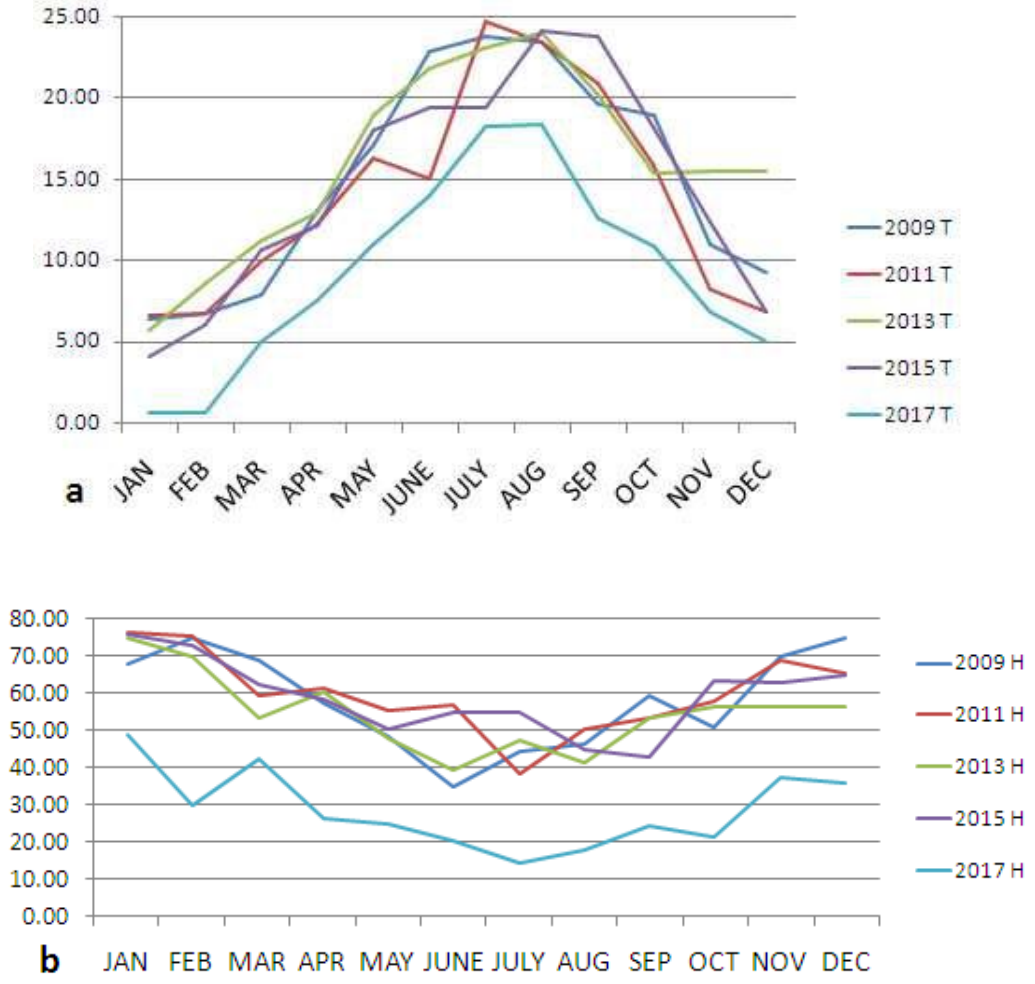

Figure 6: Monthly variation of and temperature (a) humidity (a) during the 9 consecutive years

In 2009, average monthly temperature (Figure 6a) and humidity (Figure 6b) differed between the four seasons. During winter, temperature was 6.4^{o} C and the humidity was 67.5% in January, and 9.24^{o}C, 74.7% in December. Spring recordings however showed 7.8 ^{o}C and 68.9 % in March, 13^{o}C and 57.3% in April. July and August had a temperature and humidity of 23.7^{o}C, 43.8%, and 23.04^{o}C, 46.1% respectively during the summer of 2009. Furthermore, 19.6^{o}C and 59.3% and 18.9^{o}C and 50.6% were the average temperature and humidity measured in autumn. In winter of 2011, temperature and humidity during January and February were 6.6^{o} C, 76%, and 6.75 ^{o}C, 74.9%, and 6.8^{o}C and 64.9% in December. 9.9 ^{o}C and 59.3% in March, 12.28^{o}C and 61.3% in April, represent the average temperature and humidity during spring. Moreover, summer of 2011 showed that in July, and August, temperatures and humidity were 24.6^{o}C and 38.19%, 23.4^{o}C and 49.9% respectively. In addition to that, an average of 20.8^{o}C and 53.2% in September and an average of 15.8^{o}C and 57.7% in October, were recorded in autumn 2011. Temperature and Humidity during winter of 2013 as shown in the graph, states that in January and December, we obtained an average 5.69^{o} C 74.6%, and 15.43^{o}C 55.98% respectively. Moving to spring of 2013, temperature was 11.2 ^{o}C and humidity was 53.06% in March. In summer, July, and August temperatures were 24.03^{o}C, while humidity was 46.9%, 41.2% respectively. Furthermore, autumn of 2013 showed an average of 15.35^{o}C and 56.1% in October.

Temperature and Humidity during winter of 2015 were 4.1^{o} C, 75.8%, and 6.04 ^{o}C, 75.8% in January and February. March and April showed an average temperature and humidity of 10.5 ^{o}C, 62.1%, and 12.1^{o}C, 58.1%. Meanwhile, summer of 2009 revealed that in July, and August, temperatures and humidity were 19.3^{o}C, 54.6%, and 24.06^{o}C, 44.7% respectively. Finally, autumn of 2015 showed an average of 18.1^{o}C, 63.3% in October. Temperature and Humidity during winter of 2017 were 0.5^{o} C, 48.7% in January, and 4.9^{o}C, 35.8% in December. In spring, the average temperature and humidity consisted 4.9^{o}C, 42.4% in March, and 7.5^{o}C, 26.2% in April. July, and August temperature and humidity were 18.1^{o}C, 14.1%and 18.3^{o}C, 17.3% respectively. Last but not least, autumn of 2017 showed an average temperature and humidity of 12.6^{o}C, 23.9% in September and 10.8^{o}C, 21.1% in October.

The overall average of the years 2009, 2011, 2013, 2015, 2017 included a temperature of 14.9^{o}C, 13.8^{o}C, 16.05^{o}C, 14.5^{o}C, 9.19^{o}C, and a humidity of 57.9%, 59.6%., 54.43%., 58.8%, and 28.5% respectively. As a final conclusion, temperature during winter (November, December, January and February,) decreased from 2009 till 2017. However, temperature during summer (June, July, August, and September) increased from 2009 till 2015, and then decreased from 2016 and 2017. With respect to budburst, earliness in this phenological stage was affected by the climatic conditions. In 2017 the temperature was very low in winter compared to other years, in addition to the sudden raise in temperature which led to shortening of the phenological stage budburst. This was also a product of the low precipitation during that year. On the other hand, full budburst, flowering, and fruit set occurred in the longest number of days in 2009. This was the result of the gradual change in temperature and thus budburst and flowering took the optimal time needed to occur in this year.

Due the intensely cold, short-lived winter in 2017 and then an unanticipated upsurge in temperature, premature budburst, flowering, and fruit set transpired. These conditions might have created favorable situations to break vine dormancy earlier than normally expected dates. Early season growth was slightly influenced by temperature extremes (Jones and Davis, 2000), minimal or maximal. The short winter is causing an earlier spring, so we're witnessing an increase in temperature during the final month of winter in February till mid march. Not to mention that this increase in temperature is happening during the final stage of winter so these phenomena created a shock for the vines normal functioning due to the risk of a sudden decrease in temperature in the final stage of winter. Climate of West Bekaa has been witnessing a reduction in precipitation levels and a decrease in temperature during the month of September, so autumn season occurred earlier, in September which is the final month of the summer. New climatic characteristics turned out in the past 15 years, unusual changes are happening during the 4 seasons, like rains and some heavy winds during the final month of summer and dryness during the whole season of winter. Considering the correlation between fruit maturity, budburst, fruit set and flowering, the earliness which took place in the last three stages mentioned also had an impact on harvest. This promoted a similar precedence in harvest occurrence in the 2017 season. However, this caused a disadvantage in the maturity of the fruit, in which the suitable time needed to achieve full maturity was minimized. Contrarily in 2009 harvest went through the normal time needed for maturity, not to mention the prior phenological stages which had the same outcome. This portrays 2009 as taking the highest number of days to achieve flowering.

Lebanon witnessed a mild winter in the period between 2009 till 2017. This was indicated by the low precipitation and insufficient snow on mountains tops. In addition to that, there was a prolongation in spring season which generated the formation of frost on vines, and thus resulted in a prominent damage and decrease in grape quantity. Furthermore, extreme temperature elevation during summer throughout the mentioned years provoked earlier maturity

Table 1: Correlation between all investigated indicators

	BB	FB	DF	DFS	DH	NDBF	NDBFS	
BB	1	0.51	0.77	0.46	0.56	-0.9	-0.64	BB
FB	0.51	1	0.46	0.63	0.29	-0.42	0.01	FB
DF	0.77	0.46	1	0.69	0.85	-0.41	-0.2	DF
DFS	0.46	0.63	0.69	1	0.65	-0.19	0.38	DFS
DH	0.56	0.29	0.85	0.65	1	-0.22	-0.02	DH
NDBF	-0.9	-0.42	-0.41	-0.19	-0.22	1	0.78	NDBF
NDBFS	-0.64	0.01	-0.2	0.38	-0.02	0.78	1	NDBFS

BB: beginning of budburst, FB: full budburst, DF: date of flowering, DH: date of harvest, NDBF: number of days between beginning of budburst and flowering, NDBFS: number of days between budburst and fruit set

The Table 1 shows existing correlation among various indicators (Table 1). Initially, beginning of budburst and full budburst were strongly and positively correlated with flowering, fruit set and fruit maturity dates. However, beginning of budburst was negatively correlated with the number of days between beginning of budburst and flowering and between beginning of budburst and fruit set. This was also the case in flowering which showed the same results.

With respect to the fruit set, there was a strong and positive correlation between the latter, and beginning of budburst, full budburst, flowering, fruit maturity and the number of days between beginning of budburst and fruit set. On the other hand, fruit set had a negative correlation with the number of days between budburst and flowering.

Fruit maturity was strongly and positively correlated with all the phenological stages excluding the number of days between beginning of budburst and flowering, and the number of days between beginning of budburst and fruit set.

Earliness in the four phenological stages led to an increase in the time interval of the number of days between beginning of budburst and flowering, and between beginning of budburst and fruit set.

Conclusion

Conclusively, this change in climate prompted earliness in the phenological stages which include, budburst, flowering, fruit set and fruit maturity. Additionally, premature harvest occurred in the beginning of August instead of the end of August as accustomed.

In order to adapt to these climatic variations, vines ought to be treated in the onset of each season firstly. Secondly, irrigation should be applied when there is a deprivation in precipitation. Thirdly, cultivators should utilize frost resistant varieties and avoid hydric stress during hot summers.

THE SUNFLOWER PRODUCTIVITY IN FUNCTION BY THE NUTRITION LEVEL ON CHERNOZEM CAMBIC IN LONG-TERM EXPERIENCES

Nicolai LEAH, Tamara LEAH*

Institute of Soil Science, Agrochemistry and Soil Protection "N.Dimo", Chisinau, Moldova
*Corresponding author: tamaraleah09@gmail.com

Abstract

The evaluation results on the sunflower productivity cultivated on the chernozem cambic in according to the fertilization level and agro-meteorological conditions in the years 2011-2017 are presented. Sunflower seed production obtained from the unfertilized (witness) variant ranged from 0.85 t/ha to 1.93 t/ha. Administration of fertilizers on the natural background on average for 5 years led to the increase of the sunflower yields from 1.48 t/ha to 2.47 t/ha, the production increase being 19-67%. At phosphorus levels the crop yield increased from 10% containing 1.5 mg/100g of soil to 48% - 3.0-3.5 mg/100g of mobile phosphorus soil versus the $N_{45}K_{30}$ background. In the $P_{3.5}K_{30}$ variant, the increase in harvest versus control variant was 38%. In nitrogen-based versions of PK at doses of 30-90 kg/ha the increase in sunflower production was 51-67% compared to the control variant and 13-29% relative to PK. The optimal soil phosphorus level for chernozem cambic in the sunflower cultivation was 3.0-3.5 mg/100g of soil (Machigin method) and optimal nitrogen were 45-60 kg/ha.

Keywords: *Chernozem Cambic, Fertilization, Nutrition level, Productivity, Sunflower*

Introduction

Productivity of agricultural crops largely depends on the moisture and the level of soil fertility. Research in the Republic of Moldova has shown that the average multiannual rainfall ensures obtaining of 2.7 t/ha of sunflower seed. From the account of the soil natural fertility the 1.4 tons of sunflower seeds can be obtained (Andries, 2011; Почвы Молдавии, 1986).
The untapped value of sunflower seed production under soil humidity conditions is 1.3 t/ha. This value can be covered by increasing soil fertility by fertilizer management and improving recommendations on their rational use. The agricultural soils in Moldova are relatively rich in humus, the weighted average being 3.1%. During the process of organic matter mineralization in the soils, about 74 kg/ha of the nitrogen is produced, which is not enough to produce profitable sunflower productions. According to the phosphorus content the soils of Moldova are poor. According to the results of the last cycle of the soil agrochemical cartography, about 60% of the surveyed area has an assurance degree under the optimal content of mobile phosphorus in the soils. Up to 90% of the soils are relatively optimally ensured with accessible form of potassium for plants. The main available potassium reserve is the exchangeable form, which is largely restored based on the disintegration of potassium minerals in soils of Moldova (Andries, 2007; Burlacu, 2000; Recomandări, 2012). From the soil nutrition regimes in the first minimum are nitrogen and phosphorus. In order to improve the fertilization system of the chernozem cambic (leached), the productivity and the quality of the sunflower were evaluated according to the level of fertilization and the agro-meteorological conditions of the 2011-2017 years.

Materials and methods

Field investigations were conducted within the Long-term Experimental Station of the "Nicolae Dimo" Institute of Soil Science, Agrochemistry and Soil Protection from Ivancea commune, Orhei district, founded in 1964 on the clayey-loamy cambic chernozem.

The humus content in the arable layer was 3.4%; the value of pH_{H2O} - 6.8; the sum of Ca and Mg - 37.4 me/100g of soil. In 2000 year, the experimental station was registered in the EUROSOMNET (European Soil Organic Matter Network). In the crop rotation are grown: winter wheat, corn for grain, sunflower, winter barley, rape and legumes (alfalfa, peas, beans, soybeans). The sunflower preceding culture were winter wheat and winter barley. The experiments were performed in 4 repetition. The surface of the experimental plot - 200 m^2. Investigations were carried out on the following levels of mineral nutrition: mobile phosphorus in the soil - 1.0; 1.5; 2.0; 2.5; 3.0; 3.5; 4.0 and 4.5 mg/100g of soil; exchangeable potassium in soil - 29-32 mg/100g of soil (Macighin method). The levels of mobile phosphorus in the soil were maintained by offsetting the phosphorus export from preceding culture by applying phosphorus fertilizer to the base soil tillage. Potassium fertilizers from 2010 to present do not apply in the experiments. Nitrogen doses were applied annually in doses - 0, 30, 45, 60, 75 and 90 kg/ha.

Results and discussions

The amount of rainfall, as well as their distribution during plant growing, has conditioned the sunflower's productivity. During the agricultural investigation years, agro-meteorological conditions were different. From five years of research at "Ivancea" station - two years have been relatively dry (2012 and 2015), with a humidity deficiency of 17-21% over the multiannual average, fewer droughts were 2014 and 2016. Close to normal was 2011 with 563 mm, making up 102%, over norms or so-called "wet years" were 2013 and 2017, respectively 115% and 108%. The average of 7-year atmospheric precipitations was 23 mm less than the multiannual average, constituting 529 mm (Table 1).

Table 1. Atmospheric precipitation at the "Ivancea" Station in 2011-2017 period

Multi-annual	257	100	42	100	53	100	79	100	61	100	60	100	295	100	552	100

*Note. *The period of the agricultural years is considered 01.09.2010 - 31.08.2017*

Precipitation during the cold season of the year (September-March) has created favorable humidity conditions in the early spring, which have influenced normal growth and development of sunflower plants. The amount of precipitation during the cold season at the station was almost normal, accounting for 97-114% of the multiannual average, except for 2012 with only 60% and 2015 - by 127% over the norm.

The atmospheric precipitation for the active grow period of crop field (April to August) in research years of research decreased by 7% on over the multiannual average, and by 2015 they were 55% less, constituting 134 mm. The drought effect was most pronounced in July

and August, where the monthly rainfall in the years 2015-2016 decreased by 75-95% over the multiannual average and the air temperatures exceeded the norm by 2.0-3.9^{0}C (Table 1).
The application of mineral fertilizers on the chernozem cambic has positively influenced the growth and development of sunflower culture. Sunflower production increased on average from 1.48 t/ha in the control variant to 2.47 t/ha on fertilized variants (Table 2).

Table 2. Sunflower yields on the chernozem cambic in according to fertilization level, t/ha

Variant		Year of cultivation					Average, t/ha	Increase, %

60	3,5	2,55	2,22	3,26	1,81	2,49	2,47	67
75	3,5	2,50	2,17	3,27	1,82	2,57	2,47	67
90	3,5	2,34	2,20	3,22	1,84	2,49	2,42	63

The increase in sunflower seed yield for fertilized variants increased from 19% to 67% compared to the natural background. On the phosphorus fertilization levels, the sunflower production increased from 10% on the background of 1.5 mg of mobile phosphorus to 48% - 3.5 mg/100g of soil toward the $N_{45}K_{29\text{-}32}$ fund. On the variant with $P_{3,5}K_{29\text{-}32}$ background, the increase in crop yield versus control variant was 38%. On nitrogen variants in doses of 30-90 kg/ha on the $P_{3,0}K_{29\text{-}32}$ background**,** the sunflower seed production rate was 0.76-0.99 t/ha or 51-67% against the control variant and 13-29% - versus PK variant (Table 2).
In drought years the fertilizers have significantly contributed to the formation of sunflower yield. Although the global harvest has fallen in these years, the sunflower productivity compared to the unfertilized variant in 2012 year increased by 11-60%, and in 2015 year it was doubled (from 0.85 t/ha to 1.70-1.85 t/ha). The role of phosphorus fertilizers has been decisive in the formation of sunflower production. The optimal level of mobile phosphorus in the arable layer of the cambic chernozem was 3.5 mg/100g of soil, and in the wet years the optimum phosphorus level decreased to 3.0 mg/100g of soil.
Oil content in sunflower seeds in research years ranged from 38.2% to 51.1%, the five-year average was 45.1-46.8%. In the control variant the quantity of oil was 0.3-5.4% higher compared to the fertilized variants, the average being 1.7% (Table 3).
In fertilized variants with higher yields, the seed oil content did not increase. The so-called "dilution effect" was obtained in the production of sunflower seed.
The oil content obtained per unit area is an integral indicator of crop productivity evaluation. This indicator gives the possibility to determine the agronomic efficacy or yield of fertilizers in order to obtain seed production. The administration of mineral fertilizers practically doubled the amount of oil obtained at 1 ha from the natural background (Table 4).

Table 3. The oil content of the sunflower seed cultivated on the cambic chernozem,%

Variant	Year of cultivation					Average, %
	2011	2012	2013	2015	2017	
Control	48,0	50,5	43,6	48,6	45,5	46,8
$N_{45}P_{1,0}$	46,5	50,8	39,8	47,3	46,7	46,2
$N_{45}P_{1,5}$	46,0	50,2	42,7	49,6	45,5	46,8
$N_{45}P_{2,5}$	46,8	49,3	39,2	48,1	45,8	45,8
$N_{45}P_{3,5}$	47,6	48,3	40,4	48,6	46,2	46,2
$N_{45}P_{4,5}$	46,5	50,0	41,7	47,9	47,2	46,7
$P_{3,5}$	45,5	48,3	38,2	46,2	47,2	45,1
$N_{45}P_{3,5}$	48,7	46,9	42,8	47,8	45,7	46,4
$N_{60}P_{3,5}$	46,1	49,4	39,1	45,2	46,9	45,3
$N_{75}P_{3,5}$	46,0	50,8	40,1	46,3	45,2	45,7
$N_{90}P_{3,5}$	45,9	51,1	41,1	46,4	45,5	46,0

On average, during research years on the levels of phosphorus fertilization, the amount of oil increased from 695 kg/ha to 1140 kg/ha. The role of nitrogen fertilizers was significant. The application of nitrogen fertilizers at doses of 30-45 kg/ha on the background of PK led to an increase in the amount of oil from 914 kg to 1121 kg/ha. Increasing nitrogen doses from 45 kg to 90 kg/ha did not increase the content of sunflower oil per hectare (Table 4).

Table 4. The content of sunflower oil obtained in dependence of the fertilization level, kg/ha

Variant	Cultivation year					Average, kg/ha	Increase, %
	2011	2012	2013	2015	2017		
Control	912	717	841	413	596	695,8	-
$N_{45}P_{1,0}$	1027	797	879	676	677	811,2	16,6
$N_{45}P_{1,5}$	1058	828	1008	739	805	887,6	27,5
$N_{45}P_{2,5}$	1123	937	1231	813	805	981,8	41,1
$N_{45}P_{3,5}$	1209	1096	1289	865	1196	1131	62,5
$N_{45}P_{4,5}$	1167	1115	1338	886	1194	1140	63,9
$P_{3,5}$	1055	860	1008	757	892	914,4	31,4
$N_{45}P_{3,5}$	1212	1055	1374	822	1142	1121	61,1
$N_{60}P_{3,5}$	1175	1097	1275	818	1168	1106,6	59,0
$N_{75}P_{3,5}$	1150	1102	1311	842	1161	1113,2	60,0
$N_{90}P_{3,5}$	1074	1124	1323	854	1133	1101,6	58,3

The increase of sunflower oil production from the application of mineral fertilizers increased from 16.6% to 63.9% compared to the control variant (Table 4). On the phosphorus levels ($N_{45}P_{1,0}K_{29\text{-}32}$ background), the yields increased from 10.9% to 47.3%. When applying nitrogen fertilizers at doses of 30-90 kg/ha on the $P_{3,5}K_{29\text{-}32}$, the yield of oil was decreasing compared to the administered doses and constituted 29.7-26.9%. The maximum yield of sunflower oil production was obtained on the $N_{45}P_{3,5}K_{29\text{-}32}$.

Conclusion

The application of mineral fertilizers on the natural background of cambic chernozem led to an increase in the production of sunflower seeds by 19-67%. Phosphorus fertilization levels (1.5-4.5 mg/100g of mobile phosphorus) led to 10-48% increase in sunflower yield, and nitrogen fertilizers at 30-90 kg/ha increased the seed harvest with 13-29%. The maximum yield of sunflower oil production was obtained on the $N_{45}P_{3,5}K_{29\text{-}32}$ variant. The optimal level of phosphorus in the soil for chernozem cambic in the cultivation of sunflower is 3.0-3.5 mg/100g of soil (Machigin method) and the optimal nitrogen doses are 45-60 kg/ha.

Abstract

Opuntia sp., commonly known as cactus pear, originates from Mexico and illustrates the impressive genetic diversity of Cactaceae with 400 species and a great number of varieties for Opuntia ficus indica. Moroccan cactus presents a very high genetic variability and several cultivars exist. They are distinguished by the flowering period (early, late), the flower color (yellow, orange and pink), fruit and pulp colors (green, yellow, orange, red and purple), fruit shape (oval, round or oblong), organoleptic characteristics and antioxidant content of the fruit. Cactus crop plays an important role on the ecological and economical scales, but unfortunately, in Morocco, its production is faced with a high lost due to the lack of valorization prospects. Dellahia prickly pear variety, widespread in northern Morocco, is characterized by the green pulp color of the fruit. It is among the lowest valorized cactus varieties due to the low oil content of its seeds. Therefore, its fruits are mainly used for fresh consumption. The aim of this study is to discuss the effect of the altitude on the pomological (fruit dimensions, seediness and weight) and phytochemical (juiciness, sugariness…) characteristics of the fruits of this variety in northern Morocco in order to reconsider the different possibilities to transform the excess of the production.

Key words: *Opuntia ficus-indica, Dellahia, altitude, pomology, phytochemistry.*

Introduction

Cactus pear (*Opuntia* sp.), native from Mexico, illustrates the impressive genetic diversity of Cactaceae with 400 species and a great number of varieties for *Opuntia* (Odoux et al., 1996). The prickly pear cactus (*Opuntia ficus indica*) is a plant highly distributed in the Mediterranean area, Central and South America, and South Africa (Barbera and Inglese, 1993; Muñoz de Chávez et al., 1995).The pericarp and the edible pulp of its fruit may have soft green, greenish white, canary yellow, lemon yellow, red, cherry red or purple hues (Muñoz de Chávez et al., 1995). In Morocco, this crop is witnessing a growing interest and an unprecedently spread thanks to the Green Morocco Plan. In fact, the cactus pear crop presents a lot of ecological and economical advantages. Unfortunately in Morocco, its production is faced with a high loss due to the lack of valorization prospects. Cactus pear also knows a renewed interest in several countries due to its ecological, environmental and socio-economic role: the fight against erosion and desertification, and fruit production fodder (Bouzoubaâ et al., 2014). Its ecological advantages can be attributed to its crassulacean acid metabolism, which allows CO_2 uptake at night, thus minimizing water loss during photosynthesis (Kluge and Ting, 1978 ; Winter and Smith, 1996). Low water requirements and a high water use efficiency ratio (Nobel, 1995) make cactus pear suitable for cultivation in arid and semi-arid marginal regions (Singh and Felker, 1998). In the light of changes in the global climate, cactus pear is suggested as a promising crop by the Food and Agriculture Organisation (Barbera, 1995 ; Nobel and Israel, 1994). The prickly pear is also a source of products and by-products to diverse industrial uses, medicinal, pharmaceutical and cosmetics

(Barbera, 1995). Moroccan cactus presents a very high genetic variability and several cultivars exist. They are distinguished by the flowering period (early, late), the flower color (yellow, orange and pink), fruit and pulp colors (green, yellow, orange, red and purple), fruit shape (oval, round or oblong), organoleptic characteristics and antioxidant content of the fruit. The Dellahia prickly pear variety, widespread in northern Morocco, is characterized by the green pulp color of the fruit. It is among the lowest valorized cactus varieties due to the low oil content of its seeds. Therefore, its fruits are mainly used for fresh consumption. The aim of this study is to discuss the effect of the altitude on the pomological (fruit dimensions, seediness and weight) and physicochemical (juiciness, sugariness…) traits of the fruits of this variety in northern Morocco in order to reconsider the different possibilities to transform the excess of the production.

Materials and Methods

Vegetative Material

The fruits have been collected in August 2016 at four sites with different altitudes in the North of Morocco as resumed in Tab. 1.

Tab. 1. Sites of study with their geographic coordinates and climatic characteristics

	Latitude	Longitude	Altitude (m)	Annual Rainfall (mm)	Mean Temperature (°C)
Mestassa (Mes)	35.10460	-4.41633	119	400 – 500	10 – 30
Wahran (Wah)	35.03564	-4.46452	482	500 – 600	10 – 30
Boujibar (Bou)	35.01616	-4.46961	573	600 – 700	10 – 30
Tizakhte (Tiz)	35.00597	-4.47130	712	700 – 800	10 – 30

Pomological traits measurement

From the samples kept cold at 6°C, 30 fruits per batch were randomly selected in order to determine the various physicochemical parameters. The lenght and diameter of the fruits have been measured with a digital caliper (Stainless Hardened). The weight of the whole fruits has been measured with a 0.0000g precision balance (S-203). Once weighed, the fruits have been carefully peeled manually and the peels as well as the pulp with seeds have been weighed separately. Then, the thickness of the peels was measured with a Stainless Hardened digital caliper. Then, 10 fruits per sample have been used for juice extraction. The fruits were washed, manually peeled and the pulp with seeds of each fruit was malaxed in a porcelain mortar separately then filtered. The juice obtained was quantified and kept in stoppered flasks at -4°C in a refrigerator for further analyses. The experiment was carried in triplicate and the juice yield was expressed in percentage of sample weigh. The seeds recovered from each fruit were then washed, spread on a paper and dried at room temperature for 3h. They were then manually separated from the dried pulp, weighed and counted. 10 seeds per fruit were also selected randomly and weighed separately in order to determine the mean weight of seeds. The sugar content of the juice was determined using a refractometer (DIGIT 032). The results are expressed as °Brix. The free acidity expressed as a percentage of citric acid was determined by titration; 10 mL of the juice of prickly pear was placed in a 100 ml beaker equipped with a magnetic stirrer, 20 mL of distilled water was added and the homogenized mixture is titrated with NaOH (0.1 N) to pH = 8.1 (Medina et al., 2007). For the determination of dry matter, fruits were washed and peeled. Then, 5 g of the pulp with seeds obtained was precisely weighed and placed in clean glass Petri dishes and pre-weighed. Then they were

placed in an oven at 103±1°C. After 24h, periodical weighing was carried at intervals of 2h until a constant weight. (A.O.A.C, 1990). The experiment was carried in triplicate and results have been expressed in percentage of fresh weight. As for the ash determination, it has been carried by incineration (A.O.A.C, 1990). In fact 2g of sample was placed in a porcelain crucible and incinerated in a Lenthon Thermal LTD oven at 550°C for 2 h. The porcelain crucibles were weighed again after the complete combustion in order to determine the weight of ash. Each experiment was carried in triplicate and results have been expressed in percentage of fresh weight.

Physico-chemical traits determination

Standards of sugars and organic acids commonly found in prickly pear juice were used with concentration ranges typical of the matrice indicated in Tab. 2. Standards solutions have been prepared according to their mean concentration in prickly pear juice. For each standard, three concentrations were prepared. Sugars standards solutions were prepared separately from those of organic acids.

Tab. 2. Concentrations ranges of sugars and organic acids standards solutions (g/L)

Samples preparation

The fruit pulp with seeds has been carefully crushed in a porcelain mortar by avoiding crushing the seeds. The mixture has been filtered to recover the juice. The pH of the juice extracted has been adjusted to 9 - 10 with 1 N NaOH. Then 2g of juice was taken in a test-tube and 25mL of aqueous ethanol (90% v/v) was added. The mixture was centrifugated at

8000rpm and the supernatant was recovered in a test-tube. 5mL of the supernatant was evaporated to dryness on the boiling water bath. The residue obtained was then disolved in 5mL of the mobile phase (ultrapure water), filtered through 0.45 μm membrane and finally injected in the HPLC apparatus.

Sugars determination

The HPLC system was equipped with an isocratic pump (PU 980), a variable wavelength detector UV 970 set at 210nm (for organic acids) connected in series with a refractive index detector RI 830 (for sugars) and an injection valve fitted with a 20 μL loop. Sugars have been separated on a REZEX RHM ion-exclusion column (300*7.80 mm) operating at a flow rate of 0.5mL/min by injecting 20μL of sample in the system through the valve. The refractive index detector was working at 40°C while the mobile phase was a water of chromatographic purity (ultrapure water). The chromatographic runs were performed at a column temperature of 30°C. Individual sugars were identified by comparison of their retention times with those of authentic standards under analysis conditions and quantified by external standard method. Each analyse lasted 15 min and the injections were carried out in triplicate.

Organic acids determination

The same HPLC system with the same REZEX RHM ion-exclusion column operating at a flow rate of 0.5mL/min has been used for organic acids determination. The separation was made by the variable wavelength detector UV 970 set at 210nm and working at 40°C. The mobile phase was a 0.0005 M H_2SO_4. The column temperature was initially 40°C for 5 min, then the column was heated at a rate of 5°C/min up to 60°C. 20μL of sample was injected in the system through the valve and individual organic acids were identified by comparison of their retention times with those of authentic standards under analysis conditions and quantified by external standard method. Each analyse lasted 30 min and the injections were carried out in triplicate.

Gross energy determination

The gross energy is the amount of heat produced from unit feed when it is completely burnt down to its ultimate oxidation products (CO_2 and H_2O). The feed is burnt in a closed container (Bomb calorimeter) and heat produced from it is measured (AOAC, 1995). The hydrothermal equivalent of the Parr 1341Plain Oxygen Bomb Calorimeter which represents the energy required to raise the temperature of the calorimeter one degree, usually expressed as calories per degree Celsius, was first determined by burning 1g of a standard sample (benzoic acid pellets) in the calorimeter. Then, 1g of each lyoplilised sample was compressed into pellet with a mechanical compressor and put in a cruicible to be carefully placed in the bomb calorimeter. The bomb was then closed, filled with oxygen and placed in the calorimeter bucket containing 2000mL of distilled water with 1.5°C below room temperature. The temperatures of the system were recorded with a 6775 Digital Thermometer at one-minute intervals for 5min. At the 6th minute the bomb was fired and temperatures were also recorded until a constant value. The gross energy was calculated by multiplying the rise of temperature by the equivalent hydrothermal of the system and dividing the product by the sample weigh.

$$\mathbf{He = (W \times A - 14) / (Tf - Tf)} \quad \text{and} \quad \mathbf{GE = (Tf - Ti) \times He / W}$$

With :
- He : Hydrotermal equivalent of the system (J/°C)
- A : Caloric capacity of benzoic acid (26442 J/g).
- 14 : Correction of acid formation (J)
- GE : Gross Energy (J/g)
- Tf : Final temperature (°C)
- Ti : Initial temperature (°C)
- W : Sample weight (g)

Final gross energy was expressed in Kcal/100g of dry matter.

Statistical analysis

Descriptive statistical analysis (based on calculating the mean and standard deviation for each studied parameter), the analysis of variance (ANOVA test at one way of variation : « sites ») and means comparison were all performed by the SPSS software 22. The Newman–Keuls test was used to determine significant differences between means with a 95% confidence interval.

Results and discussion

Volatile matter (%)	82.95±1.06^{a}	84.13±1.13^{a}	81.19±0.86^{a}	83.83±1.03^{a}
Dry matter (%)	17.05±1.06^{a}	15.87±1.13^{a}	18.81±0.86^{a}	16.17±1.03^{a}

The values in the same line followed by the same letter are not significantly different with a 95% confidence interval. D/L = Diameter/Lengh ; A/S= Acidity/Sugars content

No significant difference was noticed between samples about the whole fruit and pulp weight (respectively from 78.43±1.41g to 96.70±4.91g and from 52.75±2.46g to 64.74±1.40g), fruit diameter (from 46.22±0.96mm to 50.25±1.06mm), their total sugars content (from 13.56±0.9°Brix to 14.89±0.47°Brix), their free acidity (0.07±0.01 to 0.09±0.02), their volatile and dry matters (varying respectively from 81.19±0.86% to 84.13±1.13 % and from 15.87±1.13% to 18.81±0.86%). As for the ratio D/L (from 0.66±0.03 to 0.71±0.01), no significant was nor detected between samples. All fruits samples are therefore relatively oval (ratio D/L<1). Compared to previous studies, fruits weight are considerably high than those reported by Bouzabaâ et *al.* (2014) (50.58 – 64.55g).

Otherwise, the sugars content are consistent with those reported by Bouzabaâ et *al.,* (2014) (14.91 – 15.87°Brix for *Amouslem* cultivar and 13.15 – 15.87°Brix for *Moussa* cultivar) and by Mashope (2007) (11 – 16°Brix) and also by Sepúlveda and Sáenz (1990) (11 – 17°Brix). However, the sugar content is significantly influenced by cultural practices (fertilization, irrigation) and environmental factors, generally the fruits of dry lands are sweeter than those of wetlands (Mondragón et *al.,* 2001) or irrigated lands (Inglese et *al.,* 1995). Furthermore, the sugar concentration can be improved particularly by the nitrogen fertilization (Potgieter and Mkhari, 2002). The citric acid values comprised between 0.07% and 0.09% are also

consistent with those reported in the literature (0.05 – 0.18%) (Sepúlveda, 1998; Sáenz, 2000). The pH values comprised between 5.93 and 6.29 are instead relatively high compared to those reported by Bouzabaâ et *al.*, (2014) (5.80 – 5.92).
The rate of volatile matters found comprised between 81.19 and 84.13% is high compared to results reported by Bouzabaâ et *al.* (2014) (80%). This very high water content in prickly pears is a factor reflecting the high perishability of this type of fruit and therefore hinders its ability to storage at room temperature. As for the dry matter content, values found for Mestassa, Boujibar, and Tizakhte sites (respectively 17.05, 18.81, and 16.17%) are higher than the theoretical one (16%) reported by Askar and El Samahy, (1981). On the other hand, the dry matter found for Wahran site (15.87%) is lower than the theoretical one.
However, significant difference was noticed between samples about fruit lengh, their peel weigh and thickness, fruit firmity, their total seeds number, their total seeds weight, the mean weight by seed, fruits juiciness and seediness and the ratio free acidity/sugar content (A/S).
The values found for fruits lengh picked at Mestassa, Wahran and Tizakhte sites (respectively 70.69mm, 70.33mm and 70.54mm) are significantly higher than the Boujibar site one (68.58mm). Compared to the literature, these values are lower than the arverage one reported by Bekir (2006) (74.43mm). The peel weight of the the sample from Mestassa site (lowest altititude, 119m) is higher (32.77g) than the Wahran, Boujibar, Tizakhte ones (respectively 28.77, 30.56 and 28.34g). The fruits from the highest altititude (Tizakhte, 1109m) have the lowest peel weight. The values found are still lower than those reported by Bekir (2006) (37.2 to 55.24g). On the other hand, fruits from Mestassa, Wahran and Tizakhte sites have similar peel thickness (respectivement 4.82, 4.62 and 4.64mm). Those values are significantly higher than Boujibar site one (4.38mm). The peel thickness is correlated to the fruit firmity. Indeed, fruits from Boujibar wich present the lowest peel thickness also present the highest firmity (96.79%) while fruits from Mestassa presenting the highest peel thickness present the lowest firmity (95.48%). The firmity values of fruits from Wahran and Tizakhte are not significantly different (96.46 and 96.42% respectively). The values for fruits juiciness are comprised between 68.74% and 72.02%. A significant difference was found between samples, Boujibar samples being the less juicy (68.74%) and Wahran ones being the most juicy (72.02%) while Mestassa and Tizakhte samples had a similar juice rate (respectively 71.24% and 70.96%). This similarity is probably du to the sea influence on Mestassa crops (low altitude 119m) and the dew influence on Tizakhte ones (high altitude 712m). The total seeds number of Boujibar samples (323 seeds, representing 3.61% of the fruit) is significantly higher while Wahran (482m of altititude) and Tizakhte (712m of altitude) samples being thes less seedy (respctively 255 and 249 seeds representing 3.29 and 3.43% of the fruits). Mestassa samples (119m of altitude) have a total seeds number relatively high but still remains the less seedy ones (297 seeds representing 3.08% of the fruits). The total seeds weigh are comprised between 2.58 and 3.4g while the mean weigh per seed varies from 10.03 to 11.66µg Tizakhte samples (712m of altitude) being the more weighty and Mestassa ones (119m of altitude) the less weighty. The total seeds number found for Boujibar samples is higher than those reported by Bekir (2006) (187 to 262 seeds per fruit). However, values found from the other sites are consistent with those reported by Bekir (2006).

Physico-chemical traits

Tab. 5. Physico-chemical traits

Chemical traits	M	W	B	T
Glucose (mg/g DM)	63.16±5.77^{b}	60.35±4.32^{c}	68.46±2.14^{a}	61,78±6.61^{c}
Fructose (mg/g DM)	53.58±5.71^{b}	51.55±3.80^{c}	58.10±3.01^{a}	51.87±6.35^{c}
Citric acid (mg/100g DM)	185.74±10.97^{a}	176.10±9.77^{b}	126.92±4.12^{c}	64.94±2.91^{d}
Fumaric acid (mg/100g DM)	5.93±1.24^{c}	9.39±1.82^{b}	3.69±0.53^{d}	9.80±1.52^{a}
Gross energy (Kcal/100g DM)	16.49±1.15^{b}	16.21±0.17^{b}	17.94±1.65^{a}	15.09±0.21^{c}

The values in the same line followed by the same letter are not significantly different with a 95% confidence interval. DM means Dry Matter

Reports are available on nutrient composition (Benjamin and Old, 1939; Sawaya et al., 1983a), amino and non volatile acid composition (Teles et al., 1984) and soluble sugar composition (Laskshminarayana et al., 1979; Askar and El-Samahy,1981; Sawaya et al., 1983b; Wessels, 1989) of prickly pear fruit. The predominant soluble sugars in the fruit are glucose and fructose with smaller amounts of sucrose (Sawaya et al., 1983b). Other sugars such as galactose and maltose have been reported in minute amounts (Espinosa et al., 1973). Accumulation of hexoses in the final weeks of fruit development has also been reported (Barbera et al., 1992). This accumulation was probably due to seepage of mucilage from peel to the pulp (Laskshminarayana et al., 1979).

In our studies we just found glucose and fructose as the only sugars in catus pear with various content according to the altitude. Boujibar samples (573m of altitude) present the highest glucose and fructose content (respectively 68.46 and 58.10 mg/g of dry matter) while Wahran and Tizakhte ones recording the lowest content (respectively 60.35 and 61.78mg/g of DM for glucose and 51.55 and 51.87mg/g of DM for fructose). Mestassa samples have relative high content of glucose and fructose (63.16 and 53.58mg/g of DM respectively). The glucose content from Boujibar samples is higher than those reported by Gurrieri et al., (2000) (60 to 64mg/g of dry matter) but the fructose content for this site and for the other sites are consistent with those found by the same author (54 to 60 mg/g of dry matter). The glucose content Mestasaa, Wahran and Tizakhte sites are rather consistent with those reported by Gurrieri et al., (2000). Kuti and Galloway (1994) also reported data about sugars content in prickly pear juice (5.89 and 4.30mg/g of juice respectively for glucose and fructose).

A significant differencewas noticed between samples about citric acid content. The samples of Mestassa (119m of altitude) presents the highest citric acid content (185.74mg/g of DM) while Tizakhte ones presenting the lowest content (64.94mg/g of DM). We clearly see the effect of the altitude on the citric acid content. It may also be due to the nature of the soil. As for fumaric acid content, Tizakhte samples one is significantly higher (9.80mg/g of DM) while Boujibar ones presenting the lowest content (3.69mg/g of DM). Wahran samples have also a high content of fumaric acid (9.39mg/g of DM) when Mestassa samples one is relatively low (5.93mg/g of DM). Regarding the gross energy, Boujibar are significantly more caloric (17.94Kcal/100g of DM) while Tizakhte samples are the les sones (15.09Kcal/100g of DM). Values found for Mestassa and Wahran samples are not significantly different (16.49 and 16.21Kcal/100g of DM). The high gross energy of Boujibar samples can be explained, inter alia, by the their high sugars content. But, the gross energy is also influenced by the whole organic matter content of a sample while in this study we have not determined protein, lipids, among others organic matters content.

Conclusion

Samples from Boujibar site (573m of altitude) present a lot of important characteristics on pomological ant physico-chemical scales. These fruits present, among others, the highest edible part weigh (64.74g), the lowest peel thickness (4.38mm) against 4.82mm for Mestassa fruits (119m of altitude), the highest seediness (3.62%) against 3.08% for Mestassa samples (119m) and the highest firmity (96.79%) against 95.46% for Mestassa ones. Boujibar samples also presnt the highest glucose and fructose content (respectively 68.46 and 58.10mg/g of DM) and the highest gross energy (1794Kcal/100g of DM). As for citric acid content, it decreases according to the altitude, Mestassa samples having the higest content (185.74mg/100g of DM) and Tizakhte samples having the lowest content (64.94mg/100g of DM). The effect of altitude is substantial about these parameters but Tizakhte samples present situated at the highest altitude present a contradiction. This difference is probably due to dew influence on these crops, making them grow at similar conditions as if they were at sea level. We also notice that samples Tizakhte present the lowest pH value (5.93) compared to Mestassa, Wahran and Boujibar (respectively 6.29, 6.16 and 6.25). As a conclusion, the effect of altitude on the pomological and physico-chemical traits of cactus pear is notable for some traits but not for others. Other factors as soils composition or sunlight may be probably influencing these parameters.

Abstract

Variability of length of spike and number of spikelets spike^{-1} have share in forming of grain yield of wheat. The aim of this study was estimation of variability of length of spike and number of spikelets spike^{-1} in 20 genetically divergent wheat cultivars grown in different environmental conditions. The experiment was set up as a randomised block design in three replications. Obtained results indicated differences in average values of length of spike and number of spikelets spike^{-1} among tested cultivars in both years of experiment. In average for all cultivars length of spike was higher in the second year than in first year of experiment. Also, average value of number of spikelets spike^{-1} was higher in second year at the analysed wheat cultivars. The wheat cultivar Dejana expressed the highest length of spike (12.50cm) in average in the second experimental year while the wheat cultivar Sumadinka had the least length of spike (8.91cm) in average in the first year. Based on the results was established, variability of wheat cultivars for the both analysed traits of spike, as well as, significant differences between the wheat cultivars according to length of spike and number of spikelets spike^{-1}, which are in dependence of genetic and environmental factors.

Keywords: *wheat, variability, spike length, spikelets, cultivars.*

Introduction

Wheat (*Triticum aestivum* L.) is one of the most important crops as a source of food for the people worldwide. Increasing of wheat grain yield is the main task of breeders which require effort in improving characteristics of spike traits, grain, stem, leaf and root traits. The long and fertile spike potentially can contribute to improvement of grain yield of wheat (Zečević et al., 2008; Knezevic et al., 2014). Spike length together with number of spikelets and number of florets per spike represent great potential for yield improvement (Zečević, et al., 2004; Dimitrijević et al., 2011) through developing grain number spike^{-1} and as a source of assimilate in grain filling period as well as forming grain yield. Increasing of number of spikelets potentially related to increasing of number of grains (Álvaro et al., 2008). Spike length had positive relationship with number of spikelets spike^{-1} at both genotypic and phenotypic levels (Akram et al., 2008). Floral development is an important part of the pre-anthesis stage. Anther and ovary growth as well efficient pollination connected to grain number per spike, grain size and grain weight (Guo et al., 2015). Grain number per spike is related to floret survival (Gonzalez et al., 2011; Sreenivasulu and Schnurbusch, 2012). Spike structure has advantages in utilizing light in compare to other parts of plant and contribute to

increasing of yield. Also, spike together with awns contribute to longer stay green area duration. All these characteristics of spike contribute to accumulate in average 20-30% of dry matter depends of genetic and environmental factors as well as their interaction (Knezevic et al., 2015: Branković et al., 2015). The effect of genetic and environmental factor at the length of spike and development of number of spikelets per spike need further investigation. Increasing of genetic capacity of spike traits is a potential direction of increasing grain yield of wheat (Knezevic et al., 2012).

The aim of this paper was investigation of variability of length of spike and number of spikelets spike^{-1} in genetically divergent wheat cultivars grown in different environmental conditions.

Materials and methods

The twenty geneticaly divergent winter wheat cultivars were used for study of length of spike and number of spikelets spike^{-1} during two season of vegetative growth year (2015/16 and 2016/17). The experiment was performed in randomized block design in three replication on the field in Kraljevo, Serbia. The seeds of varieties were sown at the distance of 0.05m in rows of 1m length among which was the distance of 0.2m. For analysis of length of spike and number of spikelets spike^{-1} were used 60 plants in full maturity stage (20 plants per replication). For statistical analysis used MSTAT C version 5.0. The significant differences between the average values were estimated by F-test values. The analysis of variance was performed according to a random block system with one factor significant difference was tested by means of the value of LSD test.

Weather conditions

In the first year experiments 2015/206, the average temperature was 9.9 °C and the total amount of precipitation was 651.00 mm. In the second year of experiment 2016/17 average temperature was 13.0 °C and the total amount of precipitation was 523.0 mm. The average rainfall was 651.00 mm in the first year and significantly higher than in the second year (523.1 mm), and significantly higher than average values for ten years - 417.8 mm (table 1). For plants growth in the second year was more favorable regime of temperature and precipitation.

Table 1. Average monthly temperature and total monthly precipitation in Kraljevo

	Period	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Xm	Total
Temperature ^{0}C	2015/16	11.6	7.3	3.3	-0.1	8.8	7.8	14.1	15.5	21.3	**9.96**	89.64
Temperature ^{0}C	2016/17	10.6	6.8	0.0	-4.7	5.2	10.8	11.1	16.8	22.1	**8.74**	78.66
2000-2010		11.8	6.4	1.7	-0.1	2.6	5.9	11.6	16.4	20.4	**8.5**	76.5
Precipitatin (mm)	2015/16	56.8	64.0	9.0	86.2	52.7	157.9	39.9	135.9	48.6	72.3	**651.0**
(mm)	2016/17	84.1	77.6	9.4	22.0	35.0	57.0	82.0	100.0	56.0	41.1	**523.1**
2000-2010		61.0	44.3	44.6	30.0	29.9	33.2	52.9	52.6	69.3	46.4	**417.8**

During October-November, a greater amount of water residue was in the second year (161.7 mm) than in the first (120.8 mm), which represents a favorable period of germination of plants and better condition of plants for survive in the coming winter period, while during the preiod February-April amount of precipitation in the first year (250.5 mm) was higher than in the second (174.0 mm), although the distribution of rainfall was favorable in the second year of the experiment. Also, in the two months (October-November) the average temperature values were similar, wherein the sum of the temperature for the period February april 30.7 °C in the first year, more than the amount for the same period in the second year - 27.1 °C (table 1).

Results and discussion

The length of spike in the first year of experiment varied in ratio of 8.91-11.11 cm with average value 9.92 cm, while in second year varied from 10.03 to 12.50 cm with average value 11.09 cm. Number of spikelets spike^{-1} in the first year of experiment varied in interval of 20.85 - 24.38 with mean value 22.79, while in second year number of spikelets spike^{-1} varied between 21.23 and 25.0 with average value 23.53 (table 2). The obtained results showed significant differences in the average values of length of spike and number of spikelets spike^{-1} per year, that indicating diversity of studied cultivars. Similar results were reported in previous investigation of Serbian wheat genotypes (Zečević et al., 2008; Knezevic et al., 2012) as well as for Italian and Spanish wheat cultivars (Álvaro et al., 2008).

Table 2. Variability of length of spike and number of spikelets spike^{-1}

	length of spike (cm)			*Number of spikelets spike^{-1}*		
Cultivars	First year	Second year	Average	First year	Second year	Average

The significant differences among the investigated wheat cultivars were established for the length of spike (table 3). Also, the values of length spike of analysed genotypes were significant different between first and second experimental years (table 2). Generally, in average all studied wheat cultivar in both year and in average expressed higher values of length of spike. This indicates response of genotypes to environmental conditions.

Differences among cultivars according to value of spike length are affected more by genotype than by relationships to the geographic origin (Dotlačil et al., 2003). The length of spike controls by additive and nonadditive gene with prevalence of additive gene effects (Ljubičić et al., 2014). Also, the sensitivity of length of spike under environmental variation noticed (Zečević et al., 2008; Knezevic et al., 2014) and represent important components of wheat yield. The environmental factors as well temperature values, precipitation, nutrition have influence on increasing of capacity of spike (Petrović et al. 2008; Knežević et al., 2016).

Table 3. Components of phenotypic variance for length of spike (cm) of wheat – in 1st and 2nd year

Source of variance	First Year							Second Year

The significant differences among the tested wheat cultivars were established for the number of pikelet spike^{-1} in both year of experiment (table 4). The number of spikelet spike^{-1} at the analysed wheat cultivars varied and were significantly different between the cultivars between and between the years of experiment. Generally at the all tested cultivars the number of spikelet spike^{-1} in second year was the higher than in first year of experiment (table 2).

Table 4. Components of phenotypic variance for number of spikelets spike^{-1} in wheat

The investigated trait highly depended to genetic and environmental factors (Zečević et al. 2004; Dodig et al., 2008). The spike length is yield components which highly positively correlated to number of spikelets spike^{-1} (Akram et al., 2008). The spike length has strong indirect influence on yieald through number of spikelets spike^{-1} and futher on number of grain and size and weight of grain (Zečević et al., 2004). Improvements in the number of grains per spikelets mean increasing the number of grains spike^{-1}.

Conclusions

In this investigation were determined differences among wheat genotypes according to values of length of spike and number of spikelets spike^{-1}. The highest values of length of spike (12.50cm) in Dejana cultivar expressed in the first experimental year while the least (8.91cm) in wheat Šumadinka had in first experimental year. Breeding programs need conduct in the different environments in the aim of improvement of spike traits by using germplasm resources. Increasing of wheat grain yield is achievable through improving of all morphological, physiological characteristics of spike as well other organs of wheat.

Abstract

One of the main components of soil, which affects the yield of plants, is the content of organic matter. The aim of this paper was to examine the saturation of the soil with organic matter on the territory of the Nis (Serbia) in 2015. An analysis of 284 soil samples from 110 farms at the location of Nis municipality, with total area of 115,28 ha, showed that 0.4% of the samples belonged to the class of very poorly humified soil, containing organic matter up to 1%. It was also found that 50.4 % of the samples belonged to the class of poorly humified soil, with the organic matter content ranging from 1% to 3%. Furthermore, 47,9% of the analyzed soil samples belonged to the class of well-humified soil, with the humus content ranging from 3% to 5%. The lowest value was found in one of the samples from the village of Trupale in Crveni Krst, and it was 0.88%, while the samples with the highest humus value were found in the village of Hum (5.,47%). Chemical analysis was performed in 2015, in the Agricultural Advisory and Professional Service - Nis, where the humus content was determined by using the Tyurin method. Soil samples were taken from a depth of 0-30 cm in field crops and vegetable cultures, or 0-60cm in orchards. The analysis showed that the soil of this area wais not humified enough, wherefore it was necessary to pay attention to the content of humus, increased the level of organic matter with organic fertilizers and reduced losses which happened by removing and burning the crop residues.

Keywords: *Organic matter, Humus, Soil, Serbia.*

Introduction

The fraction of organic matter in the soil, which is a result of decomposition by living organisms, is called humus. Humus has a certain duration in the soil, after which it is degraded, in this way, old humus is replaced with new humus. It is desirable to maintain this balance. Soil organic matter originates from dead animal and plant residues. Microorganisms decompose organic matter, which leads to the synthesis of high molecular compounds – humus. Humus, in a broad sense, is composed of all dead organic matter in the soil, and, in a narrow sense, humus is composed of humic substances (Marković, 2016)

The amount of humus in the soil serves us to determine soil fertility. The content of organic matter in the agricultural upper layer is usually in the range of 1-6%. Humus influences the water, air and thermal regime of soil, through which it influences plant development conditions. The trend of humus decrease has been observed in nearly the entire territory of the Republic of Serbia, in the amount of 0.5-1%. This decrease of humus in the soil is very high, because humus is created slowly; as a rule, 1 cm of humus is created in 100 years (Poljosfera, 2018). In the past 20 years, the organic matter in the soil in Serbia has decreased from 3.5% to below three percent (Gulan, 2018)

A long-term, heavy use of mineral fertilizers, heavy machinery and agricultural residues burning have caused a drastic decrease in humus in the arable land at a larger territory of Serbia. The beginning of intensive land use and the use of greater quantities of mineral fertilizers, have led to the fact that these intensive methods began to destroy humus

microbiologically. Organic matter does not disappear immediately, but gradually. In countries where there is enough cattle, i.e. the soil is fertilized with manure, organic matter remains preserved (Stevanović, 2017). Burning of crop residues is considered to be an undesirable practice and is prohibited by the legislation of the Republic of Serbia (Zakon o poljoprivrednom zemljištu, 2006).

Soil fertility, i.e. humus loss, occurs because more soil nutrients are taken out of the soil than returned to it. In Serbia, the numbers of sheep, pigs and cattle are in decline, and, for this reason, soil fertilization with organic fertilizers is reduced. One of the ways to increase soil fertility is plowing crop residues (Jaćimović et al., 2017). Apart from plowing crop residues, a number of experts recommends that we "let the soil rest," which indicates a certain period when it will not be used extensively. Humus is lost faster from bare soil, so it is recommended that the soil is sown with siderate crops, which are plowed, during the "rest." Planting and plowing of siderates increase humus in the soil from 0.2 to 0.4%, depending on the plant species to be plowed (Spoljar i sar., 2011).

The holders of soil fertility are not macro- and microelements, but humus with soil microorganisms. (Serenson, 1972; SARE, 2012).

The quality of humus, in addition to humic acids, is also determined by the C:N ratio (Abdellatif et al., 2017). It is envisaged that humus contains a constant content of carbon (C), which is 58%, while the nitrogen (N) content in humus varies from 3-6%. For this reason, the C:N ratio fluctuates from 10-20. A favorable composition of humus in the soil is achieved when the C:N ratio is approaching 10; the ideal ratio is C:N = 10, favorable 10-20:1, while adverse is greater (higher) than 20:1 (Marković, 2016)

Humic matter can be divided into three groups of organic matter: humins, fulvic acids and humic acids, which are natural sources of carbon (Humic Solutions, 2016)

The influence of soil irrigation on the humus content is contradictory. Based on the results Mačkić (2016), concluded that the mean value of humus (1.11%) in the studied chernozem was lower in the surface horizons on irrigated plots, compared to non-irrigated plots (1.61%). It was assumed that the increased soil moisture stimulated microbial activity, causing faster mineralization of organic matter. Similar results were also presented by Gajić (1999); Zamfir et al., (2003); Kalinitchenko et al., (2011).

On the other hand, creating conditions for a large increase in the aboveground mass of plants and their roots, irrigation may stimulate the formation of organic matter. In soil of a lighter mechanical composition, meadows and pastures, irrigation resulted in an increase in the content of organic matter, as well as in nitrogen and phosphorous, but it did not influence the pH values of soil and the potassium content (Zhao et al., 2007).

Irrigation increased the content of organic matter in the soil primarily due to large quantities of crop residues (Denef et al., 2008; Roland et al., 2005)

Erosion also causes a reduction in organic matter in the soil, most often in agricultural soils (Bossio et al., 2010).

Needs of plants for humus are different and depend on the plant species, as well as the spreading depth of their root system. For example, in Serbia, the dominant plant species is the plum (Grčak, 2017).). Plum roots are branched and develop mostly on the surface, although roots can grow even 2 m in depth. The optimum humus content in the soil for the plum and other fruit cultures is 2.5-3%. The most needed fertilizer for the plum is nitrogen fertilizer (Gavrilović, 1959). If the soil is rich in humus, it is unnecessary to fertilize it (Blagojević and Božić, 2012).

Material and Methods

During the research, soil of farmers from the municipalities of Nis was analyzed. A total of 284 plots from 110 farms was studied, ranging in size from 0.09 to 5.89 ha. The total surface area analyzed was 115.28 ha.

Chemical analyses were performed in 2015, in the Agricultural Advisory and Professional Service - Nis, where the humus content was determined by using the Tyurin method. Soil samples were taken from a depth of 0-30 cm in field crops and vegetables, and 0-60 cm in orchards. An individual sample consisted of 20 to 25 individual samples (in lots up to 5 ha) from a depth of 0-30 cm in plots under field or vegetable crops or in plots where field or vegetable crops were planned to be grown, and from a depth of 0-60 cm, in plots under orchards or vineyards or in plots where orchards and vineyards were planned to be located.

Results and Discussion

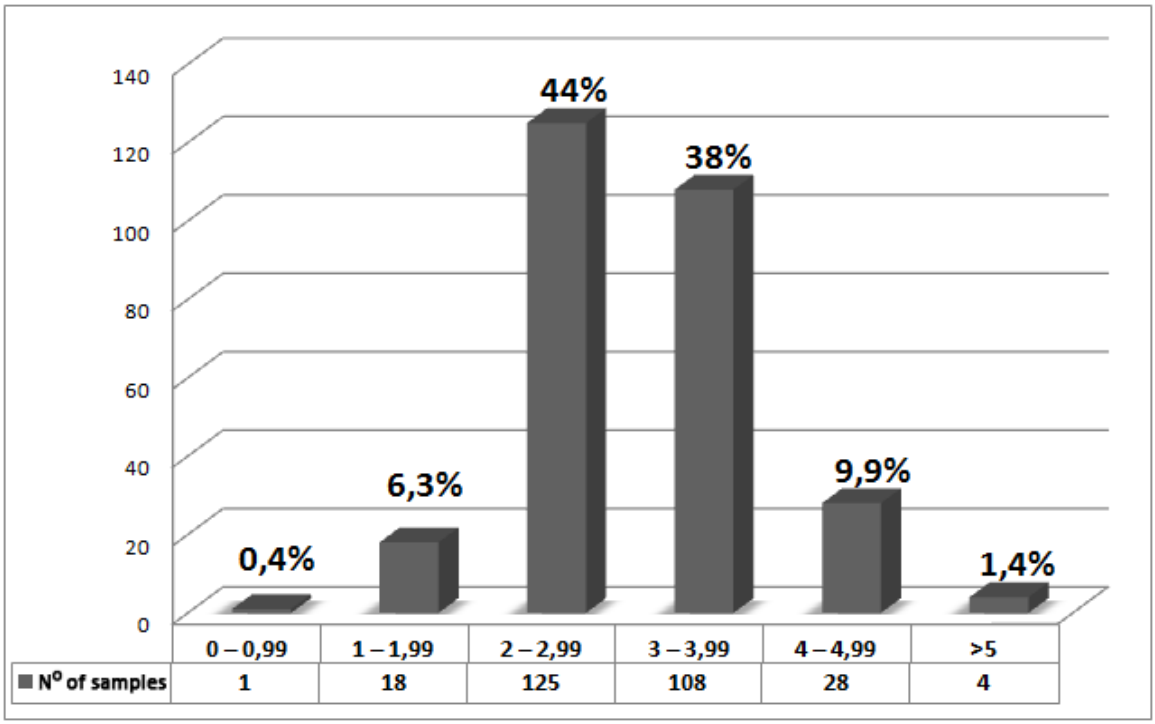
The analysis of soil inculded all 5 municipality of Niš. Most of the samples were taken from the farmlands of Crveni Krst municipality (75) and the smallest number of samples were from the local municipality of the Niska Banja (10).

As the control of soil fertility, chemical analyses of certain parameters were performed, among which was the humus content analysis. On the basis of the data obtained from a total of 248 plots on the territory of Nis, it was found that as much as 50.7% of the samples belonged to the class of land with poor or very poor humus content (below 3%). Only 1.4% of the plots belonged to the class of soil rich in humus, where the content of organic matter was higher than 5%.The lowest value was found in one of the samples from the village of Trupale in Crveni Krst, and it was 0.88%, while the samples with the highest humus value were found in the village of Hum (5.47%). The variability indicator was calculated through standard deviation using the computer, and the standard deviation was ± 0.175, which indicated that there were no major differences among the values of humus. Similar research led to similar results. The testing of humus in Central Serbia in 2015 found that a majority of samples belonged to the soil class with the percentage of soil organic matter from 3-5 (Ministarstvo poljoprivrde i zaštite životne sredine RS, 2017). The testing of the arable land in Kragujevac showed that as much as 59.5% of the samples belonged to the soil rich in humus, with its content above 3.29% (Milivojević *et al*., 2012).

Table 1. The proportion of samples that belong to certain classes of humus content, based on the analysis of 284 soil samples taken in the municipality of Niš in 2015

Soil	Number of plots	Percentage (%)	Cumulative percentage
very poorly humified (0-0.99%)	1	0.4	0.4
poorly humified (1-2.99 %)	143	50.4	50.7
humified (3-4,99 %)	136	47.9	98.6
well-humified (≥5 %)	4	1.4	100.0
Total	284	100.0	

Based on a detailed classification (Graph 1), the samples with the organic matter content ranging from 2% to 3% are dominant with 44% of all samples. Second most common samples with the organic matter contect is from ranging 3% to 4% with 38% of all samples.



Graph 1. The proportion of samples that belong to certain classes of humus content (%) in the municipality of Niš (number of samples 284).

The quantity of humus in the soil depends on the soil type, for example, in Vojvodina (Serbia), in chernozem, there is 3.5 - 5.5% of humus at a depth of 0 - 20 cm (Bajić, 2017), while in the continental part of Croatia, there is 2.99% of humus, Bensa et al. (2013). The mean content of humus in the top (surface, A) horizons of solodic soil indicates high humosity (4.43% of humus), which is a result of the presence of shallow dense grass vegetation, while the deeper horizons of solodic soil have a moderate content of humus (2.73% of humus). The humus content rapidly decreases with a depth increase (Nešić, 2004; Brady and Weil, 2008). Based on the reasrch of content of humus in Aleksinac Grčak D., and sar., (2017), which has the south-east border with the territory of Nis (Serbia), where the humus tests were performed for this study, the results are very similar. An analysis has found that 0.2% of the samples belong to the class of very poorly humified soil, containing organic matter up to 1%. It has also been found that 43.3% of the samples belong to the class of poorly humified soil, with the organic matter content ranging from 1% to 3%. Furthermore, 55.2% of the analyzed soil samples belong to the class of well-humified soil, with the humus content ranging from 3% to 5%.

Conclusions

The biggest problem in soil management in Serbia is permanent destruction of soil, its degradation and contamination. The quantity of humus has declined in a large surface area in Serbia in the last decades. The long and heavy use of mineral fertilizers, heavy equipment, burning of crop residues, irrigation in the absence of sufficient fertilizing with manure, larger quantities of nutrients being taken out of the soil than are returned to it, are the causes of the disappearance of the organic matter in soil. Based on the test results of the humus content in the soil on the territory of Nis, it was found that, on the basis of data obtained from a total of 248 analyzed plots on the territory of Nis, as much as 50.7% of the samples belonged to the class of soil whose humus content was poor or very poor (below 3%).

Due to improper use of the soil, large quantities of organic matter are removed from the soil. It is necessary to avoid crop residue burning, and reenter organic matter into the soil by plowing.

Abstract

Oxidative stability, *i.e.* shelf life of oil is related to the degree of the oxidative changes in the amount of the resulting primary and secondary oxidation products of unsaturated fatty acids. In order to improve oxidative stability, *i.e.* oil shelf life, sunflower hybrids with altered fatty acid composition have been created, *i.e.* significantly higher oleic acid (C18:1) content, even over 90% w/w, relative to the linoleic type with 25-30% w/w of oleic and 60-65% w/w of linoleic acid (C18:2). In order to examine the oxidative stability of the oil, three samples of sunflower seed oil NS hybrids (NS Oliva, NS Horizont and NS Romeo) of different fatty acid composition were analyzed. Samples were exposed to moderate temperatures (63±2°C) over a period of 8 days. Changes in the content of primary and secondary oxidation products based on changes in peroxide (PV) and anisidine (*p*-AnV) values, as well as changes in the content of conjugated dienes and trienes, were observed. The highest oxidative stability was observed in the oleic type oil sample. In this sample the determined values of the tested parameters of oxidative stability, after 8 days, were PV=4.85 mmol/kg and *p*-AnV=0.65, compared to the initial sample (PV=0.36 mmol/kg and *p*-AnV=0.57). The greatest oxidative changes occurred in the oil sample with the lowest content of oleic and the highest content of linoleic acid, as indicated by the PV=73.22 mmol/kg and *p*-AnV=3.60, after 8 days, in relation to PV=2.16 mmol/kg and *p*-AnV=0.50 in the initial linoleic type oil sample.

Keywords: *Sunflower oil, primary and secondary oxidation products, oleic acid, peroxide value, conjugated dienes.*

Introduction

Breeders all around the world try to create hybrids of sunflowers of different oil quality. The content of higher fatty acids, or their mutual relationship, is one of the basic parameters that determine the quality of the oil. Standard sunflower oil contains linoleic (62-72%), oleic (15-25%), palmitic (5-7%), stearic (4-6%) and several other higher fatty acid in traces (Purdy, 1985; Purdy, 1986; Dimić, 2005; Grompone, 2005; Miklič *et al.*, 2008; Cvejić *et al.*, 2014).
Because of the health and nutritional aspects of edible oil that is gaining increasing attention, it has become important to create the oil of the desired composition, which promotes its stability and improves nutritional value. "Standard" sunflower oil is considered to be "healthy" oil, because it contains high levels of essential fatty acid and vitamin E (*α*-tocopherol), the most important natural biological antioxidant, which functions in *in vivo* processes, while the proportion of saturated fatty acids is small (Holló *et al.*, 1998; Dimić, 2005). In Republic of Serbia, among the first in Europe, hybrids with high oleic acid content have been created, with NS Olivko the most famous, with the content of oil in the seed of 47 to 50%, and the content of oleic acid in oil exceeds 80%. This hybrid is also recognized in Italy under the name Soleado. In addition to NS Olivko, our oleic hybrids are Goleador, NS Delija and NS Oliva (Dimić, 2005, Miklič *et al.*, 2008, Cvejić *et al.*, 2014, Romanić, 2015).

In addition to increasing the nutritional value, the change in the composition of fatty acids of the oil also affects the oxidative stability of the oil. The content of oleic, linoleic and linolenic acid in oil affects its oxidative stability. Since standard sunflower oil can have up to 70% linoleic acid, it is highly susceptible to lipid oxidation. By modifying the composition of fatty acids in sunflower oil, the content of linoleic acid decreases with increasing oleic acid content, which can increase oxidative stability during storage and frying, which leads to improvement of the health status of consumers (Grompone, 2005).
Taking into account the above mentioned reasons, as well as the fact that the sunflower assortment permanently changes, the aim of this study is to analyze the oxidative stability of sunflower seeds oil of the latest NS hybrids of different fatty acid compositions based on changes in the content of primary and secondary products of oxidation at moderate temperatures. For the purpose of comparison, oxidative characteristics of oils with different oleic acid content were examined in the same way.

Material and Methods

Material: Samples of cold pressed sunflower oil of three different NS hybrids were used (NS Oliva, NS Horizont and NS Romeo). The seeds are cleaned, 6 months after harvesting and storage under normal storage conditions and without prior peeling, pressed with a worm press. The oil temperature at the output of the press was 45-50°C. Samples of cold pressed oils were taken after 72 hours of agitation at room temperature for the sedimentation, decantation and oil filtration through plain, wrinkled laboratory filter paper.
Methods: Samples of oil have been exposed in the laboratory conditions at moderate temperatures (63±2°C), in the presence of air, without the presence of light according to the methodology described by Pokorny *et al.* (1985). It was measured in 50 ml of each sample and subjected to test conditions for a period of 8 days. After the 4^{th} and 8^{th} day, the samples were taken and analysed and compared with the initial samples. The content of primary oxidation products is determined on the basis of the peroxide value (PV) (SRPS EN ISO 3960:2017) and specific absorbances at a wavelength of 232 nm, *i.e.* the content of conjugated dienes (SRPS EN ISO 3656 (2013/A1:2017). Based on anisidine value (SRPS EN ISO 6885:2017) and specific absorbances at a wavelength of 270 nm, *i.e.* the content of conjugated triers (SRPS EN ISO 3656 (2013/A1:2017), the content of secondary oxidation products has been determined. The composition of fatty acids in oils is determined by the application of gas chromatography - mass spectrometry (GC-MS) (SRPS EN ISO 12966-2:2015 SRPS EN ISO 12966-2:2017) using the HP 5890 gas chromatograph with HP 5971A mass detector ("Hewlett Packard", USA). All determinations were done in three replications, the results are tabulated as the mean value ± standard deviation, and only the mean value for the graphic representation was obtained. Statistical processing of the obtained results and graphical representations were made using Microsoft Excel 2010 (Microsoft, Washington, USA) and Statistica 13.0 (StatSoft, Tulsa, USA).

Results and Discussion

Table 1 shows the fatty acid composition of the tested samples. The highest content of oleic acid (C18:1) was found in the sample of NS Oliva and amounted to 90.04%. Oil with oleic acid content between 75.0-90.7% is defined as "high-oleic" (Codex, 1990), which classifies this sample in a group of "high-oleic" oils. The content of linoleic acid in this sample is very low, only 3.87%. The NS Horizont sample contains smaller but still significant oleic acid content of 65.63%, while the content of linoleic acid in this sample is 27.71%. According to the determined oleic acid content, the NS Horizont hybrid belongs to the category "mid-oleic" with the defined oleic acid content of 43.1-71.8% (Codex, 1999). The NS Romeo sample in its fatty acid composition is closest to the "standard" sunflower oil with 26.25% oleic acid and

66.41% linoleic acid. According to Codex (1999), oleic acid content of 14.0-39.4% and linoleic 48.3-74.0% was defined for "standard" sunflower oils, which NS Romeo sample included in this group of oils.

Table 1. Fatty acid composition (% w/w) of the tested samples

Fatty acids	**NS Oliva**	**NS Horizont**	**NS Romeo**

nd - not detected

Figure 1 shows the results and the dependence of the peroxide value and the content of conjugated dienes.

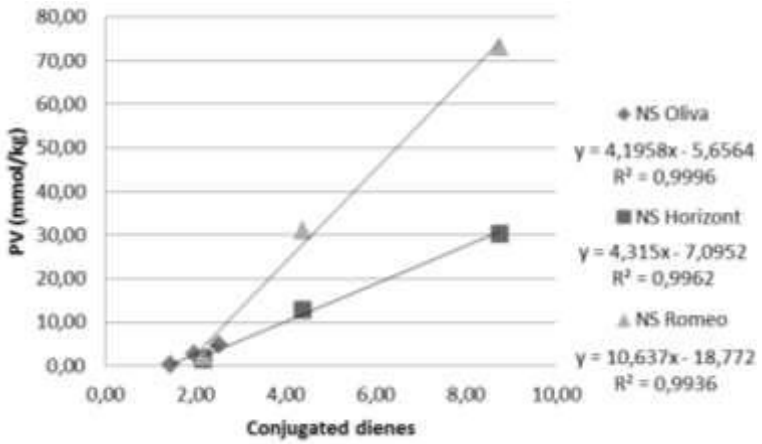

Figure 1. Results and dependence of the peroxide value and content of conjugated dienes

The highest PV in the initial samples was found in the sample NS Romeo (2.16 mmol/kg), while the lowest PV was determined in the NS Oliva sample (0.36 mmol/kg). The PV of sample NS Horizont was 1.59 mmol/kg. After 4 and 8 days, the lowest PV was found in the NS Oliva sample (2.66 and 4.85 mmol/kg) while the highest value was found in the NS Romeo sample (30.95 and 73.22 mmol/kg).

A similar situation was observed in the content of conjugated dienes. By increasing the exposure time of the test samples, the content of conjugated dienes increased. The lowest value of the conjugated dienes content in the initial samples was found in the NS Oliva sample (1.44), while the highest content of these compounds was found in the NS Romeo sample (2.69). In the NS Horizont sample, the content of conjugated dienes was 2.17. After 8 days of tempering, the trend remained the same. The largest change in content compared to the initial sample was recorded in the NS Horizont sample whose content increased 4.03 times, a slightly smaller increase was observed in the NS Romeo sample and amounted to 3.62, while the smallest increase was recorded in the NS Oliva sample, only 1.73 times.

The obtained dependence of the peroxide value and content of conjugated dienes is linear with correlation coefficient over 0,99, which indicates that the correlation between the tested parameters is very strong, Figure 1.

Figure 2 shows the results and the dependence of the anisidine value and content of conjugated trienes. The highest value of the anisidine value in the initial samples was 0.57, found in the NS Oliva sample, while the lowest value of the *p*-AnV was found in the NS Horizont sample (0.08). After 8 days, the highest value of the anisidine number was determined in the NS Romeo sample, which increased from baseline 0.5 to 3.6, while in the NS Oliva sample this increase was only a little, to 0.65.

The highest content of total trienes in the initial samples as well as after 8 days of tempering was found in the NS Romeo sample (0.23 and 0.42). The smallest content of these compounds in the initial samples was found in the NS Horizont sample (0.13). In this sample, after 8 days of tempering, the value of the content of conjugated trienes was found to be 0.31. The smallest value of the contents of these compounds after 8 days of tempering was found in the NS Oliva sample (0.28), in which the content of conjugated trienes in the initial sample was 0.21. In Figure 2 it can be seen that an insignificant linear dependence between the anisidine value and the conjugated triene content in NS Oliva and NS Horizont samples (the coefficient of correlation is less than 0.3) was found. In the NS Romeo sample, a strong correlation was found between the *p*-AnV and the content of conjugated trienes with a correlation coefficient of 0.72.

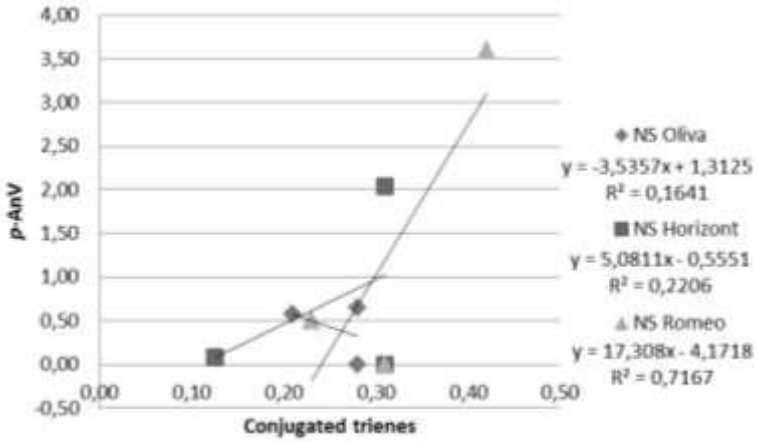

Figure 2. Results and dependence of anisidine value and content of conjugated trienes

Oxidation of oleic acid is far slower than linoleic (Romanić, 2015; Romanić and Kravić, 2017). Since, in the course of oxidation, the primary products first arise, then only secondary ones, such correlations are probably due to the high content of linoleic and low oleic acid content in the NS Romeo sample, ie the high content of oleic and low linoleic acid content in samples of NS Oliva and NS Horizont, which in any case opens the possibility of further testing. Similar results were also obtained by Romanić and Kravić (2017) who compared sunflower oil, cold-pressed high-oleic and linoleic type, and refined oil under similar conditions. The highest oxidative stability was observed in a sample of high-oleic oil. Merill *et al*. (2008) found that high-oleic sunflower oil has three times higher oxidative stability than sunflower oil of linoleic type.

Cluster method is based on PV, *p*-AnV, content on conjugated dienes and trienes in initial samples and after 4^{th} and 8^{th} day of testing. This method has determined that NS Horizont and NS Oliva samples constitute one subcluster, or from the aspect of oxidative stability, these two samples are similar in contrast to the sample NS Romeo which is separated from this group. The largest distance was recorded among NS Oliva and NS Romeo samples, 74.4 (expressed as Euclid's distance), somewhat lower distance was recorded among samples of NS Horizont and NS Romeo (46.6) while the lowest distance was 28.3 among the samples NS Oliva and NS Horizont, as can be clearly seen in Figure 3. The similarity obtained by the

clustering method among the samples of NS Oliva and NS Horizont is explained by their fatty acid composition as these samples belong to the oleic type, while the NS Romeo sample belongs to the linoleic type.

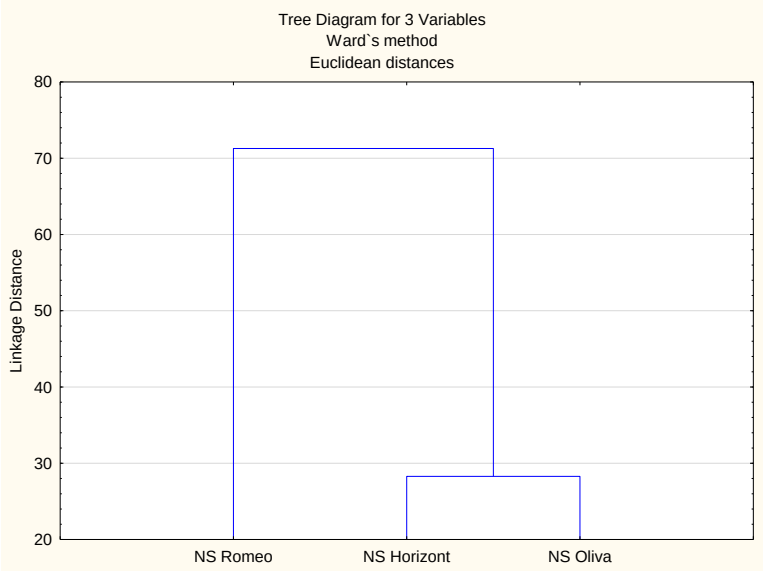

Figure 3. Cluster of oxidative stability of the tested samples

Conclusions

By comparing three NS hybrids with different oleic acid content, it was found that the best characteristics from the aspect of oxidative stability were demonstrated by NS Oliva, a sample with the highest oleic acid content (90.04%). In this sample the lowest peroxide value in the initial sample (0.36 mmol/kg) was determined, as well as for 8 days of tempering (4.85 mmol/kg). Also, the lowest value of the *p*-AnV was determined after 8 days of tempering and amounted to 0.65. The weakest characteristic was the NS Romeo sample with the lowest oleic acid content (only 26.25%). The PV in the initial sample was 2.16 mmol/kg, which represents the highest value in the initial samples, and after the 8 days of tempering in this sample, the highest PV was found at 73.22 mmol/kg. Also, in this sample the highest *p*-AnV was determined after 8 days of tempering and was 3.60.
